The GALE ENCYCLOPEDIA *of*
GENETIC DISORDERS

FIFTH EDITION

ADVISORY BOARD

Several experts in genetics and medicine have provided invaluable assistance in the formulation of this encyclopedia, from defining the scope of coverage to reviewing individual entries for accuracy and accessibility. We would like to express our sincere thanks and appreciation for all of their contributions.

PLEASE READ—IMPORTANT INFORMATION

The *Gale Encyclopedia of Genetic Disorders*, Fifth Edition is a health reference product designed to inform and educate readers about diseases and disorders with genetic origins, and about the treatments and therapies designed to deal with them. Gale believes the product to be comprehensive, but not necessarily definitive. It is intended to supplement, not replace, consultation with a physician or other health-care practitioners. While Gale has made substantial efforts to provide information that is accurate, comprehensive, and up-to-date, Gale makes no representations or warranties of any kind,

including without limitation, warranties of merchantability or fitness for a particular purpose, nor does it guarantee the accuracy, comprehensiveness, or timeliness of the information contained in this product. Readers should be aware that the universe of medical knowledge is constantly growing and changing, and that differences of opinion exist among authorities. Readers are also advised to seek professional diagnosis and treatment for any medical condition, and to discuss information obtained from this book with their health-care provider.

FOREWORD

We are at the dawn of a Golden Age of genetic and genomic science and medicine. Once the stuff of science fiction, sequencing the entire human genome is now a relatively routine, though nonetheless remarkable, procedure. Genetic research has opened a veritable treasure chest—and in some instances, a Pandora’s box—of new scientific and medical insights.

It’s long been known that heredity affects health. Genetics—the study of single genes and their effects on the body and mind—explains how and why certain traits such as hair color and blood type run in families. Genomics—the study of more than single genes—considers the functions and interactions of all the genes in the genome. Epigenetics studies heritable characteristics that influence gene expression through mechanisms other than alterations of a DNA sequence. Epigenetics decodes how environmental factors influence the expression and function of genes, contributing to health or illness.

At the outset of the Human Genome Project in 1993, scientists speculated that human cells likely contained upwards of 100,000 unique, protein-encoding genes. However, by the conclusion of the project only about 22,300 genes were identified. Why so great a discrepancy? The English language uses only 26 distinct letters, but their combinations give rise to roughly 170,000 words (not to mention an additional 47,000 now considered obsolete). Similarly, the human genome, with only about one-fifth as many genes as originally thought, combines their functions into multigene genomic systems.

Understanding the interconnectedness of genomic systems promises far greater insight and clinical scope than genetics for the diagnosis and treatment of disease. Medical genomics draws on our ever-expanding knowledge of the entire genome and deepens our understanding of commonly occurring diseases such as breast and colorectal cancer, Parkinson’s disease, and Alzheimer’s disease. Genomics also plays a role in diseases once believed to be caused entirely by infectious pathogens (disease-causing agents), such as the human immunodeficiency virus (HIV) and tuberculosis. Rather than simple

cause-and-effect relationships, these frequently occurring disorders are now understood to result from interactions between multiple genes and environmental factors. Genetic variations frequently play a protective or a causative role in the expression of diseases.

A common approach in medicine has been to divide diseases into three broad categories: diseases that are primarily genetic in origin; those primarily attributable to environmental causes; and those arising from the interplay between genetics and the environment. With our advancing understanding of genomics and epigenetics, the previously clear distinctions between these categories are shrinking. It’s becoming apparent that the way genes interact with one another, with the environment, and with the biological conditions in which they operate is a better way to understand the subtleties, and sometimes the patient-specific characteristics, of disease.

This encyclopedia considers some of the disorders believed to be predominantly genetic in origin and others that are the result of genes interacting with environmental factors.

Another way to characterize genetic disorders is by their pattern of inheritance, as single gene, multifactorial, chromosomal, or mitochondrial. Single-gene disorders (also known as Mendelian or monogenic disorders) are caused by mutations in the DNA sequence of just one gene. Because genes control the synthesis of proteins, a mutated gene may produce a protein that is unable to carry out its intended function, resulting in a disorder. The dysfunctional version of the gene that causes the disorder is referred to as a mutant or as a disease allele (an allele is a gene variation, most of which do not cause disease). There are more than 10,000 known single-gene disorders including cystic fibrosis, sickle-cell anemia, and Huntington’s disease.

Multifactorial or polygenic disorders result from a complex combination of environmental factors and mutations in multiple genes. For example, many genes that influence susceptibility to breast cancer have been identified, rendering a patient’s risk more difficult to

analyze and address than single-gene or chromosomal disorders. Some of the most common chronic diseases that are multifactorial in origin include heart disease, Alzheimer's disease, arthritis, diabetes, and cancer.

Chromosomal disorders are produced by abnormalities in chromosome structure, missing or extra copies of chromosomes, or errors such as translocations (the repositioning of a DNA sequence from one chromosome to another). Down syndrome is a chromosomal disorder in which an individual has an extra, third copy of chromosome 21. (This tripling is why Down syndrome is also known as trisomy 21.)

Mitochondrial disorders result from mutations in the non-chromosomal DNA of mitochondria, organelles involved in aerobic cellular energy production. Compared with the other patterns of inheritance, mitochondrial disorders occur infrequently.

Although many diseases, disorders, and conditions are termed “genetic,” classifying a disease as genetic simply means that there is an identified genetic component to its origin or its expression. Many medical geneticists contend that most diseases cannot be classified as either strictly genetic or environmental. The expression of a genetic disease can sometimes be altered, even to the point of complete suppression, by environmental factors. Similarly, diseases due to infectious pathogens may not be expressed because of a genetic predisposition for a protective immune response. Each disorder, in each individual, exists along a continuum spanning a range of genetic and environmental causes.

Today, in the third decade of the 21st century, the possibility of preventing and changing genetic legacies appears within reach of modern medical science. Genomic medicine predicts the risk of disease in the individual, whether highly probable, as in the case of some of the well-established single-gene disorders, or as an increased susceptibility likely to be influenced by environmental factors. The great promise of genomic medicine is to make preventive measures more powerful and treatment more specific to the individual, enabling investigation and treatments that are custom-tailored to an individual's genetic susceptibilities, or to the characteristics of the specific disease or disorder. Genomic analyses can personalize medicine, accurately predicting which individuals will respond to certain therapies or survive certain infections and it can inform development of new treatments.

Among the many exciting advances in clinical genetics and genomics are the increased use of polygenic risk scoring to identify individuals at risk for heart disease, cancer, and other chronic conditions. Liquid biopsies, which detect DNA that has escaped from cells, offer a less invasive way to detect cancers and monitor

the effectiveness of treatment. CRISPR/Cas9 (an acronym that stands for “Clustered Regularly Interspaced Short Palindromic Repeats/CRISPR-Associated Protein 9”) technologies can be used to edit genomes. Efforts are currently underway to use them to address single-gene disorders. After early setbacks, gene therapy has now proven to be a successful approach to treatment for hemophilia and spinal muscular atrophy.

Today, molecular technologies that rapidly identify viral pathogens are in use worldwide. For example, pathogen genomics were used to track the Ebola virus epidemic in West Africa between 2014 and 2015. More recently, genomic sequencing decoded the genes of SARS-CoV-2, the virus that causes COVID-19, enabling scientists to detect and monitor the spread of genetic variants. The mRNA (messenger RNA) technology used to create lifesaving COVID-19 vaccines encodes information that teaches the body to synthesize harmless antigens that mimic vulnerable portions of the actual virus, thereby stimulating the body's production of virus-neutralizing antibodies. This technology is being applied to develop vaccines and treatments for a wide range of pathogens, from HIV, Zika, malaria, and tuberculosis to influenza and cancer—in less time and at lower costs than traditional methods.

The widespread availability and direct-to-consumer marketing of genetic and genomic tests that do not require a prescription or referral from a physician present new opportunities, but also pose new challenges. Personal genomic tests may be used by people seeking to learn more about their ancestry and their health (specifically their carrier status, disease risk, and response to drugs). Proponents of such testing maintain that people who learn more about their genetic risks will take steps to improve their health and well-being. Skeptics worry about the stress that such knowledge can create and how the results of testing may be used.

Advances in genetics and genomics research and treatment raise a host of ethical, legal, and social questions and considerations. For example, is it appropriate to perform tests for conditions for which no treatment exists? How should we interpret and act on test results, such as an individual's increased susceptibility to a disease that is associated with several genes and environmental triggers? How do we ensure just and fair access to genomic science and treatments, especially for those with fewer resources? How do we resolve concern about the use of genome-editing technologies for heritable genetic changes? How do we understand and communicate the influence of genomics on concepts of race and ethnicity? How do we respect intensely personal cultural and religious differences of opinion about the use of genomic data to inform medical decision making?

This encyclopedia aims to inform and educate readers about the origins of genetic disorders and the promise and progress made to detect and treat them. We also hope that it will inspire discussion and debate about

wise and judicious use genetic and genomic research and technologies.

Barbara Wexler, MPH

INTRODUCTION

The Gale Encyclopedia of Genetic Disorders is a unique and invaluable source for information regarding diseases and conditions of a genetic origin. This collection of 575 entries provides in-depth coverage of disorders ranging from exceedingly rare to very well-known. In addition, several non-disorder entries have been included to facilitate understanding of common genetic concepts and practices such as chromosomes, genetic counseling, and genetic testing. Also included are two entries new to the fifth edition that discuss issues of race: “Race and genetics” debunks the idea that race is a genetic or biological characteristic, and “HeLa cells” discusses the contribution of Henrietta Lacks to genetic research and the ways in which medical ethics have evolved.

This encyclopedia avoids medical jargon and uses language that laypersons can understand, while still providing thorough coverage of each disorder in a manner medical professionals will find beneficial as well. *The Gale Encyclopedia of Genetic Disorders* fills a gap between basic consumer health resources, such as single-volume family medical guides, and highly technical professional materials.

Each entry discussing a particular disorder follows a standardized format that provides information at a glance. The rubrics used include:

- Definition
- Description
- Genetic profile
- Demographics
- Signs and symptoms
- Diagnosis
- Treatment and management
- Prognosis
- Resources
- Key terms

INCLUSION CRITERIA

A preliminary list of diseases and disorders was compiled from a wide variety of sources, including professional medical guides and textbooks, as well as consumer guides and encyclopedias. The advisory board, made up of medical and genetic experts, evaluated the topics and made suggestions for inclusion. Final selection of topics to include was made by the advisory board in conjunction with Gale, Part of Cengage Group editors.

ABOUT THE CONTRIBUTORS

The essays were compiled by experienced medical writers including genetic counselors, physicians, and other health-care professionals. The advisors reviewed the completed essays to insure they are appropriate, up-to-date, and medically accurate.

HOW TO USE THIS BOOK

The Gale Encyclopedia of Genetic Disorders has been designed with ready reference in mind.

- Straight **alphabetical arrangement** of topics allows users to locate information quickly.
- **See also terms** at the end of an entry direct the reader to related articles.
- A list of **key terms** are provided where appropriate to define unfamiliar terms or concepts. Additional terms may be found in the **glossary** at the back of volume 3.
- The **resources** section directs readers to additional sources of medical information on a topic.
- Many entries contain “**Questions to Ask Your Doctor**” sidebars, which provide patients or caregivers with pertinent questions for their medical professionals.

- Valuable **contact information** for organizations and support groups is included with most entries. The appendix contains an extensive list of **organizations** arranged in alphabetical order.
- A comprehensive **general index** guides readers to all topics and persons mentioned in the text.

GRAPHICS

The Gale Encyclopedia of Genetic Disorders contains more than 350 full-color illustrations, including photographs and pedigree charts. A complete symbol guide for the pedigree charts can be found in the appendix.

ALPHABETICAL LIST OF ENTRIES

A

18p deletion syndrome
18q deletion syndrome
22q11.2 deletion syndrome
22q13 deletion syndrome
3-M syndrome
3-Methylglutaconic aciduria type 2
3D organoid biosystems
46,XX testicular disorder of sex development
Aarskog syndrome
Abetalipoproteinemia
Absence of vas deferens
Accutane embryopathy
Aceruloplasminemia
Achondrogenesis
Achondroplasia
ACHOO syndrome
Acrocallosal syndrome (ACLS), Schinzel type; Joubert syndrome; and related disorders
Acromegaly
Adams-Oliver syndrome
Adaptive immunity
Adelaide-type craniosynostosis
Adenylosuccinate lyase deficiency
Adrenoleukodystrophy
Agenesis of the corpus callosum
Aicardi syndrome
ALA dehydratase deficiency
Alagille syndrome
Albinism
Alcoholism
Alexander disease
Alkaptonuria
Alpha thalassemia
Alpha-1 antitrypsin deficiency
Alpha-thalassemia X-linked intellectual disability syndrome
Alport syndrome
Alström syndrome
Alzheimer's disease
Ambiguous genitalia
Amelia
Amelogenesis imperfecta
Amniocentesis
Amyloidosis
Amyotrophic lateral sclerosis
Androgen insensitivity syndrome
Anencephaly
Angelman syndrome
Ankylosing spondylitis
Apert syndrome
Arginase deficiency
Arnold-Chiari malformation
Arthrogryposis multiplex congenita
Arthropathy-camptodactyly syndrome
Asperger syndrome
Asplenia
Asthma
Astrocytoma
Ataxia-Telangiectasia
Attention deficit hyperactivity disorder
Atypical Singleton-Merten syndrome
Autism spectrum disorders
Autologous germline mitochondrial transfer
Autosomal dominant multiple pterygium syndrome
AUTS2 syndrome

B

Bardet-Biedl syndrome
Base editing
Beare-Stevenson cutis gyrata syndrome
Beckwith-Wiedemann syndrome
Beta thalassemia
Bicuspid aortic valve
Biotinidase deficiency
Bipolar disorder
Birt-Hogg-Dubé syndrome
Bloom syndrome
Blue rubber bleb nevus syndrome
Brachydactyly
Branchiootorenal (BOR) syndrome
Breast cancer
Bruton agammaglobulinemia

C

Campomelic dysplasia
Camurati-Engelmann disease
Canavan disease
Cancer
Cancer genetics
Cardiofaciocutaneous syndrome
Carnitine palmitoyltransferase deficiency
Carpenter syndrome
Caudal dysplasia
CECR1 gene-recurrent fevers and strokes in children
Celiac disease
Cell-free DNA test
Cenani-Lenz syndrome

Central core disease
Cerebral autosomal dominant
arteriopathy with subcortical
infarcts and leukoencephalopathy
(CADASIL)
Cerebral palsy
Channelopathies
Charcot-Marie-Tooth disease
CHARGE syndrome
Chediak-Higashi syndrome
Chondrodysplasia punctata
Chondrosarcoma
CHOPS syndrome
Chorionic villus sampling
Choroideremia
Chromosomal abnormalities
Chromosome
Cleft lip and palate
Cleidocranial dysplasia
Clubfoot
Cockayne syndrome
CODAS syndrome
Coffin-Lowry syndrome
Coffin-Siris syndrome
Cohen syndrome
Cole-Carpenter syndrome
Colitis
Collagenopathy, types II and XI
Coloboma
Color blindness
Combined pituitary hormone
deficiency
Computational genomics
Cone-rod dystrophy
Congenital adrenal hyperplasia
Congenital contractural
arachnodactyly
Congenital heart disease
Congenital hypothyroid syndrome
Congenital microcoria
Conjoined twins
Connectome genetics
Corneal dystrophy
Cornelia de Lange syndrome
Costello syndrome
Cowden syndrome
Crane-Heise syndrome
Craniofacial microsomia
Craniosynostosis

Creutzfeldt-Jakob disease
Cri du chat syndrome
Crispr/Cas
Crohn's disease
Crouzon syndrome
Crouzonodermoskeletal syndrome
Cystic Fibrosis
Cystinosis
Cystinuria

D

Dandy-Walker malformation
De novo
Dementia, hereditary forms
Dent disease
Dentatorubral-pallidoluysian atrophy
Depression
Diabetes
Diamond-Blackfan anemia
Diastrophic dysplasia
Direct-to-consumer genetic testing
Disorders of sex development (DSD)
DNA (deoxyribonucleic acid)
DNA methylation
Donohue syndrome
Down syndrome
Duane syndrome
Dubowitz syndrome
Duchenne and Becker muscular
dystrophy
Dyschondrosteosis
Dysplasia
Dystonia

E

Ectodermal dysplasia
Ectrodactyly-ectodermal dysplasia-
clefting syndrome
Edwards syndrome
Ehlers-Danlos syndrome
Ellis-van Creveld syndrome
Emery-Dreifuss muscular dystrophy
Encephalocele
Epidermolysis bullosa
Epigenetic inheritance
Epigenome

Epilepsy
Erythropoietic porphyria
Erythropoietic protoporphyria
Essential hypertension
Essential tremor
Ex vivo lentiviral gene therapies
Exome sequencing
Expanded carrier screening (ECS)

F

Fabry disease
Facioscapulohumeral muscular
dystrophy
Factor V Leiden thrombophilia
Familial adenomatous polyposis
Familial dysautonomia
Familial idiopathic basal ganglia
calcification
Familial lipoprotein lipase
deficiency
Familial Mediterranean fever
Fanconi anemia
Fanconi-Bickel syndrome
Feingold syndrome
Fetal alcohol spectrum disorders
FG syndrome
Fibroblast growth factor receptor-
related conditions
First-trimester pregnancy screening
Fluorescent in situ hybridization
Focal dermal hypoplasia
Fragile X syndrome
Fraser syndrome
Freeman-Sheldon syndrome
Friedreich ataxia
Frontonasal dysplasia
Frontotemporal dementia
Fryns syndrome

G

Galactosemia
Galactosialidosis
Gamete donor anonymity
Gastric cancer
Gastroschisis
Gaucher disease

Gene
Gene editing
Gene fusion
Gene mutations
Gene panel testing
Gene pool
Gene regulatory networks
Gene therapy
Genetic anthropology
Genetic counseling
Genetic disorders
Genetic gain
Genetic Information Nondiscrimination Act (GINA)
Genetic mapping
Genetic testing
Genetics and congenital anomalies
Genome
Genome sequencing
Genome- and epigenome-wide association studies
Genomic medicine
Genotype and phenotype
Genotype tissue expression project (GTEx)
Germline genome editing
Germline mosaicism
Giant congenital melanocytic nevus
Glanzmann thrombasthenia
Glaucoma
Glycine encephalopathy
Glycogen storage diseases
GM1-gangliosidosis
Greig cephalopolysyndactyly
Griscelli syndrome

H

Haim-Munk syndrome
Hair loss syndromes
Hallermann-Streiff syndrome
Hand-foot-genital syndrome
Harlequin ichthyosis
HeLa cells
Hemihypertrophy (Hemihyperplasia)
Hemochromatosis

Hemolytic-uremic syndrome
Hemophilia
Hepatocellular carcinoma
Herceptin
Hereditary angioneurotic edema
Hereditary colorectal cancer
Hereditary coproporphyrria
Hereditary desmoid disease
Hereditary hearing loss and deafness
Hereditary hemorrhagic telangiectasia
Hereditary hypertrophic cardiomyopathy
Hereditary multiple osteochondromas
Hereditary neuropathy with liability to pressure palsies
Hereditary pancreatitis
Hereditary spastic paraplegia
Hereditary spherocytosis
Hermansky-Pudlak syndrome
Hirschsprung disease
Holoprosencephaly
Holt-Oram syndrome
Homocystinuria
Human Genome Project
Huntington's disease
Hutchinson-Gilford progeria syndrome
Hydrocephalus
Hydrolethrus syndrome 1 (HLS1)
Hydrops fetalis
Hyperlipoproteinemia
Hyperoxaluria
Hyperphenylalaninemia
Hypochondrogenesis
Hypochondroplasia
Hypophosphatasia
Hypophosphatemia
Hypospadias and epispadias

I

Ichthyosis
Imprinting
Incontinentia pigmenti
Infertility

Inheritance
Inherited arrhythmia

J

Jackson-Weiss syndrome
Jacobsen syndrome
Jervell and Lange-Nielsen syndrome
Joubert syndrome

K

Kabuki syndrome
Kallmann syndrome
Karyomapping
Karyotype
Keppen-Lubinsky syndrome
Klinefelter syndrome
Klippel-Feil syndrome
Klippel-Trenaunay-Weber syndrome
Kniest dysplasia
Krabbe disease

L

L1 syndrome
Langer-Saldino achondrogenesis
Larsen syndrome
Laterality sequence
Leber congenital amaurosis
Leber hereditary optic atrophy
Leigh Syndrome
Lesch-Nyhan syndrome
Leukodystrophy
Li-Fraumeni syndrome
Limb-girdle muscular dystrophy
Liquid biopsy
Lissencephaly
Long QT syndrome
Lowe oculocerebrorenal syndrome
Lupus
Lynch syndrome

M

Macular degeneration—age-related
Major histocompatibility complex

Male infertility
 Malignant hyperthermia
 Mannosidosis
 Marfan syndrome
 Marshall syndrome
 Marshall-Smith syndrome
 MCAD deficiency
 McCune-Albright syndrome
 McKusick-Kaufman syndrome
 Meckel's diverticulum
 Meckel-Gruber syndrome
 Melanoma
 Menkes syndrome
 Metaphyseal dysplasia
 Methemoglobinemia, beta-globin type
 Methylenetetrahydrofolate reductase variant (MTHFR gene variant)
 Methylmalonic acidemia
 Micro syndrome
 Microbiome
 Microcephaly
 Microcephaly and hypomyelination
 Microcephaly with spastic diplegia
 Microdeletion and microdeletion syndromes
 Microphthalmia with linear skin defects
 Miller-Dieker syndrome
 Mitochondrial disease
 Mitochondrial replacement therapy (MRT)
 Moebius syndrome
 Monosomy 1p36 syndrome
 Mowat-Wilson syndrome
 Moyamoya
 mRNA vaccine technology
 Mucopolidosis
 Mucopolysaccharidoses
 Muir-Torre syndrome
 Multifactorial inheritance
 Multiple endocrine neoplasia
 Multiple epiphyseal dysplasia
 Multiple lentigines syndrome
 Multiple sclerosis
 Multiplex ligation-dependent probe amplification

Muscular dystrophy
 Mutations (on-target and off-target)
 Myasthenia gravis
 MYH9-related disorders
 Myopia
 Myotonia congenita
 Myotonic dystrophy
 Myotubular myopathy

N

Nail-patella syndrome
 Nance-Insley syndrome
 Narcolepsy
 Nephrogenic diabetes insipidus
 Neu-Laxova syndrome
 Neural tube defects
 Neurofibromatosis
 Neuronal ceroid lipofuscinoses
 Nevoid basal cell carcinoma
 Next-generation sequencing
NGLY1 deficiency
 Niemann-Pick disease
 Nijmegen breakage syndrome
 Noninvasive prenatal screening
 Noonan syndrome
 Norrie disease
 Nucleic acid therapies

O

Obesity
 Oculodentodigital syndrome
 Oligohydramnios sequence
 Omphalocele
 Oncogene
 Opitz syndrome
 Oral-facial-digital syndrome
 Organic acidemias
 Ornithine transcarbamylase deficiency
 Osteoarthritis
 Osteogenesis imperfecta
 Osteoporosis
 Osteosarcoma
 Otopalatodigital syndrome
 Ovarian cancer

P

Pallister-Hall syndrome
 Pallister-Killian syndrome
 Pancreatic beta cell agenesis
 Pancreatic cancer
 Panic disorder
 Pantothenate kinase-associated neurodegeneration
 Parkes Weber syndrome
 Parkinson's disease
 Paroxysmal nocturnal hemoglobinuria
 Patent ductus arteriosus
 Pedigree analysis
 Pelizaeus-Merzbacher disease
 Pendred syndrome
 Pervasive developmental disorders
 Peutz-Jeghers syndrome
 Pfeiffer syndrome
 Pharmacogenetics
 Pharmacogenomics
 Phenylketonuria (PKU)
 Pierre-Robin sequence
 Poland anomaly
 Polycystic kidney disease
 Polycystic ovary syndrome
 Polydactyly
 Polygenic risk scoring
 Pompe disease
 Pontocerebellar hypoplasia (PCH)
 Porphyrias
 Prader-Willi syndrome
 Preimplantation genetic diagnosis
 Prenatal ultrasound
 Primary ciliary dyskinesia
 Primary familial brain calcification
 Primordial dwarfism
 Prion diseases
 Propionic acidemia
 Prostate cancer
 Protein C deficiency
 Protein S deficiency
 Proteus syndrome
 PRPS1 gene mutation—progressive hearing loss
 Prune-belly syndrome
 Pseudo-Gaucher disease
 Pseudoachondroplasia

Pseudoxanthoma elasticum
PTSD (post-traumatic stress disorder)
Pulmonary arterial hypertension
Pyloric stenosis
Pyruvate carboxylase deficiency
Pyruvate dehydrogenase complex deficiency
Pyruvate kinase deficiency

R

Race and genetics
Raynaud's disease
Recurrence risk counseling
Refsum disease
Renal agenesis
Renal failure due to hypertension
Renal-hepatic ciliopathy
Renpenning syndrome
Retinitis pigmentosa
Retinoblastoma
Rett syndrome
Rheumatoid arthritis
Rhizomelic chondrodysplasia punctata
Rhodopsin
Rieger syndrome
RNA (ribonucleic acid)
Roberts SC phocomelia
Robinow syndrome
Rothmund-Thomson syndrome
Rubinstein-Taybi syndrome
Russell-Silver syndrome

S

Saethre-Chotzen syndrome
Schinzel-Giedion syndrome
Schizophrenia
Schwartz-Jampel syndrome
Scleroderma
Sclerosing bone dysplasias
Scoliosis
Seckel syndrome
Selfish gene theory
Septo-optic dysplasia
Severe combined immunodeficiency

Short-rib thoracic dysplasia with or without polydactyly
Shprintzen-Goldberg craniosynostosis syndrome
Sialidosis
Sickle cell disease
Simpson-Golabi-Behmel syndrome
Single genome sequencing
Sirenomelia
Sjögren-Larsson syndrome
Skeletal dysplasia
Smith-Fineman-Myers syndrome
Smith-Lemli-Opitz syndrome
Smith-Magenis syndrome
Sotos syndrome
SPARCA1 spectrin-associated autosomal recessive cerebellar ataxia type 1
Spastic cerebral palsy
Spina bifida
Spinal and bulbar muscular atrophy
Spinal muscular atrophy
Spindle transfer technique
Spinocerebellar ataxia
Spinocerebellar ataxia 3
Spondyloepiphyseal dysplasia
Spondyloepiphyseal dysplasia congenita
SRY (sex-determining region Y)
Stargardt disease
Stem cells

SYMBOL GUIDE FOR PEDIGREE CHARTS

Pedigree charts are visual tools for documenting biological relationships in families and the presence of disorders. Using these charts, medical professionals such as geneticists and genetic counselors can analyze the genetic risk in a family for a particular trait or condition by tracking which individuals have the disorder and determining how it is inherited.

A standard set of symbols has been established for use in creating pedigree charts. Those found within the

body of several entries in the encyclopedia follow the symbol guide explained on the next page.

The exact style and amount of information presented on the chart varies for each family and depends on the trait or condition under investigation. Typically, only data that is directly related to the disorder being analyzed will be included. For more information, see the “Pedigree analysis” entry in the third volume.

Symbol Guide for Pedigree Charts

	Male		Miscarriage
	Female		Pregnancy terminated due to affected condition
	Affected male		Elective termination of pregnancy
	Affected female		Female with no children by choice
	Carrier male		Female with no children due to medical infertility
	Carrier female		Identical twin females
	Deceased male		Fraternal twin females
	Deceased female		Consanguineous relationship
	Male adopted into a family		Relationship no longer exists
	Female adopted into a family		Unknown family history
	Gender not specified		d.79y Died at 79 years
	Pregnancy		dx.41y Diagnosed at 41 years
	Four males		Relationship line Line of descent Sibship line Individual line
	Three females		

18p deletion syndrome

Definition

18p deletion syndrome involves a range of signs and symptoms resulting from a deletion of all or part of the short arm (p) of chromosome 18. These signs and symptoms vary greatly, depending on the extent of the deletion. However, they often include a short stature, distinctive facial features, and mild-to-moderate intellectual impairment. 18p deletion syndrome is also called partial monosomy of chromosome 18 or simply 18p.

Description

The 23 pairs of human chromosomes—one member of each pair from the mother and one from the father—carry the genes that confer the information for making all of the proteins in the body. A small constriction called the centromere divides each chromosome into a long arm (q) and a short arm (p). 18p deletion syndrome is caused by a missing piece from the short arm of one of the two members of the chromosome 18 pair. In comparison, 18q deletion syndrome is caused by a missing piece from the long arm of chromosome 18. The term “De Grouchy syndrome” can refer to either 18p or 18q deletion syndromes. The term “partial monosomy of chromosome 18p” indicates that the deleted genes are present only on the intact chromosome 18.

An 18p deletion may include all or only part of the short arm of chromosome 18, with signs and symptoms of the syndrome dependent on the specific genes that are missing. Like most other chromosome abnormalities, 18p increases the risk of birth defects, developmental delays, and learning disabilities, although specific problems vary greatly depending on the size of the deletion.

Genetic profile

Although the cause of 18p deletions is not known, in 85% of reported cases, the parents’ chromosomes are normal. Thus, the syndrome has usually not been inherited

from a parent with an 18p deletion. Rather, the deletion has arisen spontaneously, presumably during formation of the parental egg or sperm cell. This is called a *de novo* or spontaneous deletion. For this reason, parents of a child with 18p deletion syndrome are usually not at increased risk of having another child with the condition. In a small number of cases, the mother has been found to have an 18p deletion (as of 2015, there had been no reports of 18p fathers). In the case of an 18p parent, each of that parent’s offspring has a 50% risk of inheriting 18p deletion syndrome. Sometimes a parent of a child with 18p deletion syndrome is found to have a common chromosome abnormality known as a balanced translocation, in which genetic material has been exchanged between chromosomes. Because there is no significant gain or loss of genes, the translocation does not cause any symptoms in the parent. However, formation of the parent’s egg or sperm cells may be affected. In such cases, the likelihood of having another child with a chromosome 18 abnormality is greatly increased. It is also possible for 18p deletions to occur during fetal development, in which case only some cells in the body have the deletion. This is called mosaic 18p deletion syndrome.

In most people with 18p deletion syndrome, the 18p is the only chromosome abnormality. However, sometimes the deletion results from a more complex chromosome rearrangement, such as an unbalanced translocation. Such a rearrangement may cause not only 18p but also the duplication of another piece of a chromosome. The symptoms of such a rearrangement are difficult to predict, since the affected individual may have characteristics of a chromosome duplication as well as a deletion.

Chromosome 18 contains about 2.5% of the total DNA of a cell. The short (p) arm is estimated to have about 100 genes, whereas the long (q) arm contains 300–500 genes. Thus far, all reported cases of 18p are missing the chromosome tip (distal portion). Studies have suggested that many people with 18p deletion syndrome—but by no means all—have a chromosome 18 that broke off at a “hot-spot” near the centromere known as 18p11.1. Researchers

are trying to correlate the breakpoints in 18p and the lost genes with symptoms. For example:

- Patients with a deletion that leaves intact the chromosome region 18p11.1–18p11.21 have normal intelligence or only very minor learning difficulties compared to patients with deletions in this region.
- Holoprosencephaly (HPE), a malformation of the forebrain that also affects facial features, has been mapped to the most distal portion of 18p (the tip) in at least some patients.
- A round face appears to also be due to deletion of a distal region.
- Growth retardation and seizures appear to correlate with loss of the distal half of 18p.
- Drooping of the upper eyelid (ptosis) and a short neck have been mapped to loss of the proximal (closest to the centromere) half of 18p.
- Dystonia (abnormal muscle tone or contraction), which affects a few patients with 18p deletion syndrome, has been mapped to a region that includes the *DYT7* gene.

Demographics

18p deletion syndrome is very rare, affecting about 1 in 50,000 births. Since the first report of the syndrome by Jean de Grouchy and his research team in 1963, more than 150 case studies have been published. Approximately 60% of reported cases are female, and the actual ratio of affected females to males may be higher.

Signs and symptoms

Symptoms and their severity vary greatly. Many traits associated with 18p deletion syndrome are relatively non-specific and are affected by multiple genes on multiple chromosomes, contributing to symptom variability. There have even been reports of people with 18p with few or no symptoms who were not diagnosed until they had severely affected children. Many symptoms of 18p deletion syndrome are similar to those of 18q deletion syndrome. About 80% of 18p deletion syndrome patients have vision problems, especially strabismus (imbalanced eye muscles). Other common symptoms include:

- short stature, sometimes due to growth hormone deficiency
- a round face
- large ears
- ptosis
- mild-to-moderate intellectual impairment, although IQ scores vary from normal to severely impaired
- developmental delays
- speech delay and communication difficulties
- sinking in of the sternum in the chest (pectus excavatum or funnel chest)

- curvature of the spine
- hypotonia (low muscle tone)
- frequent ear infections in infants and children
- foot abnormalities

Serious brain and spinal cord abnormalities affect 10% to 15% of patients. About 10% of patients have brain malformations associated with HPE, in which the brain fails to completely divide into hemispheres. This leads to cleft lip, cleft palate, a flat nasal bridge, and closely spaced eyes. Between 10% and 25% of patients have heart defects. Other reported symptoms include:

- pituitary hormone deficiencies
- thyroid problems
- a small head (microcephaly)
- wide-set eyes (hypertelorism)
- an extra skin fold at the inner corner of the eye (epicanthal fold)
- short, webbed neck
- small jaw
- palate abnormalities
- dental abnormalities
- enlarged tonsils
- a broad trunk
- minor genital abnormalities, especially in males
- hand abnormalities
- hair abnormalities
- breathing problems including asthma
- digestive problems, especially chronic constipation
- juvenile arthritis
- deficiency in immunoglobulin A (IgA) antibodies, which can increase susceptibility to infection
- behavior problems, including aggressive behaviors and temper tantrums
- social and emotional problems
- hyperactivity and attention deficit
- sleep problems
- autism spectrum disorder
- seizures in a small number of children

Diagnosis

Examination

The most common characteristics of 18p deletion syndrome are non-specific and may not be obvious at birth. Even characteristic facial features may not become apparent until about age three. A complete neurological exam is used to detect and evaluate neurologic deficits.

KEY TERMS

18p—A deletion from the short arm of chromosome 18.

18q—A deletion from the long arm of chromosome 18.

Autism spectrum disorder—A variable developmental disorder that includes an impaired ability to communicate and form normal social relationships.

Centromere—A constricted region of a chromosome that is involved in cell division and is used to define the long arm (q) and short arm (p) of the chromosome.

Chromosomes—Linear structures of genetic material in the cell nucleus, consisting of DNA and proteins; human cells have 23 pairs of chromosomes, with one member of each pair contributed by each parent.

Cleft lip—Tissue of the upper lip that does not fuse during prenatal development.

Cleft palate—Abnormal development of the roof of the mouth that leaves an opening.

De Grouchy syndrome—Deletions in chromosome 18, originally identified in the 1960s by the French geneticist Jean de Grouchy.

Fluorescent in situ hybridization (FISH)—A technique used to visualize chromosome abnormalities.

Holoprosencephaly; HPE—An extremely variable developmental defect in the formation of the brain and face. The forebrain does not grow forward or divide completely into hemispheres.

Karyotype—The visual characteristics of the chromosomes of a cell.

Microcephaly—A small head.

Monosomy—The presence of only one chromosome of a pair. 18p is a partial monosomy, since it is the absence of a portion of one chromosome.

Preimplantation genetic diagnosis (PGD)—In vitro fertilization followed by genetic analysis of the resulting embryos to ensure that only healthy embryos are implanted in the mother's uterus.

Ptosis—A drooping upper eyelid.

Translocation—Transfer of part of a chromosome to another position, especially on a different chromosome. A balanced translocation does not result in the loss or duplication of any genetic material. However, an unbalanced translocation does involve loss or gain of genetic material.

Tests

Karyotyping visualizes the chromosomes in cells and can detect chromosome abnormalities such as rearrangements and deletions. Cytogenetic fluorescent in situ hybridization (FISH) can supply detailed information about the deleted chromosome region. A microarray called an array-CGH determines the exact DNA base pairs that are deleted. The parents' chromosomes are analyzed to determine whether the 18p was inherited or spontaneous.

Procedures

Various procedures are performed depending on the patient's suspected abnormalities. Procedures include magnetic resonance imaging (MRI) of the brain and spinal cord or an echocardiogram to detect heart defects. An electroencephalogram (EEG) may be performed if there is a risk of seizures.

Treatment and management

Traditional

Treatment and management depend on the specific symptoms. Surgeries can correct some abnormalities. Plastic surgery can correct craniofacial abnormalities,

specifically ptosis, cleft lip, or palate. Some children require special supportive footwear or braces for orthopedic problems. Regular screening is important for detecting vision, hearing, thyroid, and other problems. Extra dental care is very important. Physical, occupational, and speech therapies, special-needs education, and supportive care can alleviate other symptoms of 18p deletion syndrome.

Drugs

Drug therapy also depends on the symptoms. Children may be treated with growth hormone to prevent short stature. Anti-seizure medications can reduce or eliminate seizures.

Prognosis

The prognosis for 18p deletion syndrome depends on the specific symptoms and their severity. Severe congenital effects may cause death before or shortly after birth. However, early death is the exception. In the absence of serious brain abnormalities, such as severe HPE, most people with 18p deletion syndrome have normal life-spans. Many people with 18p have only mild or moderate learning difficulties and can live active and independent or semi-independent lives.

QUESTIONS TO ASK YOUR DOCTOR

- What information will genetic tests provide about my child's syndrome?
- Did my child inherit 18p deletion syndrome from me or my partner?
- What are the chances that I will have another child with 18p deletion syndrome?
- What medical treatments and developmental supports will my child require?
- What is my child's prognosis?

Prevention

Sometimes 18p is detected prenatally by chorionic villus sampling or amniocentesis, and craniofacial abnormalities may be visible on prenatal ultrasounds. In most cases, 18p is not inherited from an affected parent and is caused by a spontaneous, unpredictable chromosome deletion. However, parents of a child with 18p deletion syndrome will be tested to see if either has an 18p deletion or chromosomal rearrangement that resulted in their child's syndrome. If so, they are at high risk of having another child with the deletion and may choose to have prenatal or preimplantation genetic diagnosis (PGD). PGD requires in vitro fertilization, embryo biopsies to obtain chromosome karyotypes, and subsequent implantation into the mother's uterus of one or more embryos with normal chromosomes.

Margaret Alic, PhD

18q deletion syndrome

Definition

18q deletion syndrome includes the signs and symptoms caused by deletions of the long arm (q) of chromosome 18. The extent of the 18q deletion varies, affecting as many as 500 genes. Therefore, symptoms and severity also vary greatly, but may include mental disability or developmental delays, facial and limb abnormalities, hearing problems, and short stature, among others. 18q deletion syndrome is known by a variety of names including chromosome 18q-syndrome, monosomy 18q, De Grouchy syndrome, or simply 18q.

Description

Chromosomes are the structures that contain genes. A gene is made up of DNA and produces a protein. Chromosomes are thus structures that organize DNA in particular combinations for particular purposes. The 23 pairs of human chromosomes—one member of each pair is contributed by each parent—are numbered from one to 22 and then X and Y for the sex chromosomes. Observing the physical structure of a chromosome, one sees a small constriction, called the centromere, which divides each chromosome into a long arm (q) and a short arm (p). 18q deletion syndrome is caused by a missing piece of the long arm of one of the two members of the chromosome 18 pair. Most 18q deletions occur near the end of the long arm and are called distal 18q. Deletions near the centromere—known as proximal 18q—are very rare, with only a couple dozen cases described since proximal 18q was first identified in 1974. Because 18q deletions affect varying numbers of genes, symptoms of the

syndrome vary from mild to severe. For instance, some patients have intellectual disability (an IQ score below 70–75) and developmental delays, whereas others may have only very mild intellectual deficiencies or even normal intelligence and development. Many patients have distinctive facial features, such as a wide nose and mouth or a cleft palate.

Genetic profile

The cause of an 18q deletion is unknown. It typically occurs spontaneously, during formation of the egg or sperm in a parent or very early in embryonic development. Thus, most patients do not have a family history of the syndrome. It is not passed down from one generation to the next and is not likely to occur in siblings. In rare cases, however, a child may inherit the 18q deletion from a mildly affected parent or from a parent carrying a chromosomal rearrangement that does not involve the loss or gain of genetic material and produces no symptoms. If the 18q deletion occurs during fetal development, the affected individual may have a mixture of cells with and without the deletion. In most cases, the 18q deletion is the only chromosome abnormality. However, in some cases, the deletion is the result of a more complex rearrangement of chromosome 18. This, in turn, results in less predictable signs and symptoms.

Chromosomes are divided into “bands.” Distal 18q deletions usually start at bands 21 to 23 and extend to include the tip of the long chromosome arm. Proximal deletions usually involve chromosome segments between the centromere and band 21.1, leaving the tip of the chromosome intact.

Demographics

18q deletion syndrome is very rare, occurring in only about 1 in 40,000 births. Nevertheless, it is the second most common abnormality of chromosome 18 after trisomy 18 (an extra chromosome 18).

Signs and symptoms

Symptoms

Depending on which genes are missing, symptoms of a distal 18q deletion may include:

- short stature, possibly resulting from a growth hormone deficiency
- leukodystrophy—degeneration of white matter in the brain and spinal cord—which may be caused by the loss of a gene called myelin basic protein. This protein is important for the production of myelin that covers, protects, and insulates nerve fibers
- developmental delays

KEY TERMS

Aural atresia—The absence of the external ear canal.

Autism spectrum disorder—A variable developmental disorder that includes an impaired ability to communicate and form normal social relationships.

Centromere—A constricted region of chromosomes that is involved in cell division and is used to define the long arm (q) and short arm (p) of a chromosome.

Cleft lip—Tissue of the upper lip that does not fuse during prenatal development.

Cleft palate—Abnormal development of the roof of the mouth that leaves an opening.

De Grouchy syndrome—Deletions in chromosome 18, originally identified in the 1960s by the French geneticist Jean de Grouchy.

Distal 18q—A deletion of the end of the long arm of chromosome 18, including the tip.

Fluorescent in situ hybridization (FISH)—A technique that is used to visualize chromosome abnormalities.

Genital hypoplasia—Underdeveloped genitals.

Intellectual disability—A lack of normal mental development, usually defined as an IQ score below 70–75.

Leukodystrophy—Loss of myelin (white matter) in the brain, spinal cord, or peripheral nervous system.

Microcephaly—A small head.

Midfacial hypoplasia—Subnormal growth of the central face.

Myelin—The white, fatty, covering of nerve fibers.

Proximal 18q—A deletion within the long arm of chromosome 18, near the centromere.

- cognitive impairment including intellectual deficits
- autism spectrum disorder
- head and facial abnormalities, which can include an unusually small head (microcephaly), large protruding ears, widely spaced and deep-set eyes, a wide and downturned mouth, cleft lip and/or palate, and mid-facial hypoplasia.
- eye movement disorders or other vision problems
- skin problems
- limb, hand, and foot deformities, such as clubfoot or shortened thumbs

- hearing loss and aural atresia—absence of an external ear canal—often accompanied by malformation of the ear
- ear and sinus infections
- underdeveloped genitals (genital hypoplasia), especially in males
- heart defects or heart disease
- poor muscle tone, sometimes accompanied by mild obesity, poor reflexes, or tremor
- gastrointestinal problems such as reflux or hernias
- thyroid problems
- low levels of immunoglobulin A (IgA) antibodies, causing susceptibility to infection
- seizures
- behavioral problems, such as aggressiveness, tantrums, and/or hyperactivity

Proximal 18q deletions present different symptoms than distal 18q deletions. Proximal 18q deletions affect brain development and function. Children may have developmental delays, some degree of cognitive impairment, and speech problems. Patients with proximal 18q frequently have poor muscle tone. Seizures are much more common than with distal 18q deletions, affecting about half of patients with proximal 18q deletion syndrome. Heart defects are rare and problems with the genitourinary tract are less common in patients with proximal 18q deletion syndrome. Patients may have foot abnormalities. Although patients may have small stature, this does not appear to due to growth hormone deficiency. Vision problems are common with patients with proximal 18q deletion syndrome. However, hearing loss is less common than with distal 18q.

Diagnosis

Examination

Distinctive facial features—which may be evident only on close examination—as well as other physical abnormalities and developmental delay may help with a preliminary diagnosis. However, a confirmed diagnosis of 18q deletion syndrome requires a genetic test.

Tests

18q deletion syndrome is diagnosed by examining the chromosomes in cells using fluorescent in situ hybridization (FISH).

Procedures

Magnetic resonance imaging (MRI) is used to determine the extent of myelin deficiency in the central nervous system.

QUESTIONS TO ASK YOUR DOCTOR

- My baby has been diagnosed with 18q deletion syndrome; what types of developmental delays can I expect?
- What types of screenings should my child have and how often?
- At what age can my child safely be given growth hormones and how effective are they?
- Does my child require surgery for hearing loss?
- Are there any alternative treatments?
- Will my child always require seizure medication?

Treatment and management

Traditional

Although 18q deletion syndrome cannot be cured, many of the symptoms are treatable. For example, aural atresia can be relieved by surgery, called canalplasty, that creates a normal-sized ear canal. Plastic surgery can correct cleft lip or palate, midfacial hypoplasia, and other craniofacial abnormalities. Regular screening is important for detecting vision, hearing, and other problems. Extra dental care is very important. Physical therapy, special-needs education, and supportive care can alleviate other symptoms of the condition.

Drugs

Drug therapy depends on the symptoms. Children with distal 18q are often treated with growth hormone to prevent short stature. Anti-seizure medications can reduce or eliminate seizures.

Prognosis

Prognosis varies depending on the specific symptoms and their severity. Some characteristics of 18q, such as growth hormone deficiency, can be effectively treated. However, other symptoms, such as developmental delay or intellectual disability, may be lifelong. Most children with 18q who are in good health and have no major birth defects live into adulthood. The majority of patients with distal 18q die at a young age. The distal deletions include the transcription factor 4 (*TCF4*) gene, which leads to more complex medical and developmental problems, including breathing problems.

Prevention

Since 18q deletion syndrome is not usually inherited from an affected parent, there is no prevention. Although genetic testing for 18q can be performed on the amniotic fluid early in pregnancy, there is usually no reason to suspect the syndrome unless one parent is known to carry a chromosome 18 deletion or other chromosomal abnormality. In most cases, the risk that a couple will have a second child with 18q deletion syndrome is very low. However, if one parent has an 18q deletion, there is a 50% chance that each of his or her children will have the deletion.

22q11.2 deletion syndrome

Definition

22q11.2 deletion syndrome is a relatively common genetic disorder characterized by congenital heart defects, palate abnormalities, distinct facial features, immune problems, learning disabilities, and other abnormalities. This syndrome is caused by a deletion of chromosomal material from the long arm of chromosome 22 (22q) that leads to a wide spectrum of effects.

Description

22q11.2 deletion syndrome is also known as velocardiofacial syndrome, DiGeorge syndrome, Sphrintzen syndrome, conotruncal anomaly face syndrome, and the CATCH-22 syndrome. Because of the wide variability in the features of this syndrome, medical professionals originally thought that 22q11.2 deletion syndrome was more than one syndrome, and it was separately described by a number of physicians—Dr. DiGeorge, Dr. Sphrintzen, and others. Dr. DiGeorge described the more severe end of 22q11.2 deletion syndrome (infants with congenital heart defects, unusual facial features, and immune system abnormalities). The term velocardiofacial (VCF) syndrome was used for the milder end of 22q11.2 deletion syndrome. These individuals usually had palate anomalies, distinct facial features, and learning disabilities.

22q11.2 deletion syndrome is an extremely variable syndrome. The main features are congenital heart defects, distinctive facial features, and palate (roof of the mouth) problems. Other problems include immune system abnormalities, thyroid problems, kidney abnormalities and learning difficulties including mild developmental delay. Very rarely do individuals have all of the problems associated with this syndrome. Most individuals with 22q11.2 deletion syndrome have only a few of the associated features. Some individuals with 22q11 deletion syndrome are very mildly affected, and others are more severely affected. The reason for the wide variability in this syndrome is not known.

Genetic profile

22q11.2 deletion syndrome is a genetic disorder caused by a deletion of chromosomal material from the

KEY TERMS

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Conotruncal heart abnormality—Congenital heart defects particularly involving the ventricular (lower chambers) outflow tracts of the heart includes subarterial ventricular septal defect, pulmonic valve atresia and stenosis, tetralogy of Fallot and truncus arteriosus.

Velo—Derived from the Latin word *velum*, meaning palate and back of the throat.

long arm of chromosome 22. A series of genes are located in this region. Individuals with 22q11.2 deletion syndrome may have some or all of these genes deleted. This syndrome is sometimes called a microdeletion syndrome or a contiguous gene syndrome. Contiguous refers to the fact that these genes are arranged next to each other. The size of the deletion can be large or small, which may explain why some individuals with 22q11.2 deletion syndrome are more severely affected than others. The exact genes responsible for this syndrome are not known.

22q11.2 deletion syndrome is an autosomal dominant disorder. Genes always come in pairs and in an autosomal dominant disorder only one gene needs to be missing or altered for an individual to have the disorder. About 10%–15% of the time, deletion of the long arm of chromosome 22 that causes this syndrome is inherited from a parent. If a parent has 22q11.2 deletion syndrome, then there is a 50% chance they will pass the deletion on to each of their children who will also be affected with 22q11 syndrome. For reasons that are not understood, it is possible for a parent with mild features of 22q11.2 deletion syndrome to have a child with severe features of the syndrome.

Although 22q11.2 deletion syndrome is an autosomal dominant disorder, over 85%–90% of individuals with this disorder are the only individuals in their family with this disorder. When this is the case, the chromosome deletion that causes 22q11.2 deletion syndrome is called *de novo*. A *de novo* deletion is one that occurs for the first time in the affected individual. The causes of *de novo* chromosome deletions are not known. Parents of a child with 22q11.2 deletion syndrome due to a *de novo* deletion are very unlikely to have a second child with 22q11.2 deletion syndrome.

Demographics

22q11.2 deletion syndrome is one of the most common chromosomal deletion syndromes. It is estimated that approximately 1 in 2,000 to 1 in 6,000 individuals has a deletion of chromosome 22q11. Approximately 130,000 individuals in the United States have 22q11.2 deletion syndrome. Because of the extreme variability of this syndrome, it is possible that individuals with milder features are under diagnosed and the exact incidence of this disorder is not known. As more physicians become familiar with this syndrome, it is likely that more individuals will be correctly diagnosed.

Individuals with 22q11.2 deletion syndrome are diagnosed based upon physical findings. Of infants born with congenital heart defects, 5% will be found to have a deletion of chromosome 22q11. Of infants with a cleft palate, approximately 5%–8% of them will be found to have a 22q11 deletion.

Signs and symptoms

22q11.2 deletion syndrome is a multisystem disorder. It is also sometimes referred to as velocardiofacial syndrome. This name reflects the organ systems that are most commonly affected in 22q11.2 deletion syndrome. “Velo” is from the Latin word *velum*, which means “palate” and back of the throat, “cardio” refers to the heart, and “facial” refers to the distinctive facial features of individuals with 22q11.2 deletion syndrome. While it may seem unusual that these three separate areas are affected, a possible explanation lies in the early development of the embryo. Very early in development, the cells that will become the heart, face and thyroid lie next to each other in a region called the neural crest. As the embryo continues to develop, these cells migrate or move to become organs (the heart, face, and palate). It is believed that the deletion of chromosomal material from chromosome 22q causes a problem in the migration of these cells leading to the variability of features or problems seen in 22q11.2 deletion syndrome.

In addition to the heart, palate, and face, many other organ systems can also be affected including the kidneys, the immune system, the brain, the throat, the skeletal system, the skin, the genitourinary system and the endocrine (hormone) system. It is not possible to cover every possible feature of 22q11.2 deletion syndrome, but the following is an overview of the most common features.

The characteristic facial features seen in individuals with 22q11.2 deletion syndrome include a long face with narrow palpebral fissures (the opening for the eyes), a prominent nasal bridge (the arch of the nose between the eyes), a slightly bulbous nasal tip, a long nose, small ears with thick helical folds, and a small jaw. None of these

features individually is abnormal, but the combination of features is characteristically seen in individuals with 22q11.2 deletion syndrome. These features may not be present or as easily noticeable in African-American individuals with 22q11.2 deletion syndrome.

Approximately 70% of individuals with 22q11.2 deletion syndrome have palate abnormalities. These may include complete cleft palate (an opening of the bones and skin of the roof of the mouth) or a submucous cleft palate (an opening of only the bones of the roof of the mouth covered by skin). Other individuals with 22q11.2 deletion syndrome have more subtle palate and throat abnormalities including velopharyngeal insufficiency, which is a problem in the coordination between the tongue, palate, and throat muscles. All of these problems can lead to feeding problems in infancy and speech problems such as hypernasal speech.

Cardiac or congenital heart defects are one of the more serious symptoms of 22q11.2 deletion syndrome and affect about 75% of individuals. There is a wide range of cardiac abnormalities seen in 22q11.2 deletion syndrome. Some are minor and may require no treatment, some are correctable by surgery, and others are invariably fatal. The most common heart defects seen in individuals with 22q11.2 deletion syndrome are truncus arteriosus, interrupted aortic arch, tetralogy of Fallot, ventricular septal defects (VSDs), pulmonary stenosis and patent ductus arteriosus. Many of these heart defects are known as conotruncal heart defects. Conotruncal refers to the type of embryonic cells that were involved in the development of these regions of the heart.

Immune problems are another of the serious problems associated with this syndrome. Because of the underdevelopment of the thymus gland, individuals with 22q11.2 deletion syndrome can have reduced amounts of the cells necessary to fight infections—T cells. Because of this reduction in T cells, individuals with 22q11.2 deletion syndrome are more prone to getting infections and less able to fight them off. The degree of immune deficiency can be variable with some individuals having life-threatening infections and others having much milder problems.

Growth problems may be seen in children with 22q11.2 deletion syndrome. Infants with 22q11.2 deletion syndrome are often diagnosed as having failure to thrive. This may result from feeding problems due to their palate abnormalities but they can also have gastroesophageal reflux and vomiting problems. It also appears that individuals with 22q11.2 deletion syndrome have generalized growth problems. Most adult individuals with 22q11.2 deletion syndrome have short stature.

Individuals with 22q11.2 deletion syndrome can also have specific learning disabilities and possibly mild developmental delay. The learning disabilities are specific. Most individuals with learning disabilities have a discrepancy between their performance IQ score (higher) and their verbal IQ score (lower) that indicates a nonverbal learning disability. Simple IQ testing may not reveal this learning disability and it is important to evaluate the components of IQ scores separately. Individuals with 22q11.2 deletion syndrome seem to do better at verbal learning and do well in subjects such as reading. They have more trouble with abstract concepts such as math.

Individuals with 22q11.2 deletion syndrome are also at risk to develop psychological problems and mental illness. 22q11.2 deletion syndrome has been associated with higher rates of bipolar affective disorder, manic-depressive illness, and schizoaffective disorder when compared to individuals who do not have 22q11.2 deletion syndrome. Other mood disorders, such as depression, also occur at a higher incidence in individuals with 22q11.2 deletion syndrome. Most of these disorders appear during adolescence or adulthood. Some individuals with 22q11.2 deletion syndrome are mildly mentally retarded. Others have learning disabilities and some are diagnosed as having attention deficit hyperactivity disorder.

Endocrine problems are also commonly seen. The endocrine system is the hormone producing system of the body and is composed of glands such as the thyroid and parathyroid. Individuals with 22q11.2 deletion syndrome may either be missing one or more of these glands or have underactive glands. An underactive thyroid is called hypothyroidism and an underactive parathyroid is called hypoparathyroidism. Because the parathyroids help to regulate the level of calcium in the body, individuals with 22q11.2 deletion syndrome also have problems with their calcium levels. Low levels of calcium can lead to seizures.

Individuals with 22q11.2 deletion syndrome may also have kidney problems such as a cystic kidney, missing (aplastic) kidney, or malformed kidney. They can have limb differences such as extra fingers or ribs, or problems with the vertebrae in the back that might lead to scoliosis.

Diagnosis

The diagnosis of 22q11.2 deletion syndrome is usually made by a physician familiar with the syndrome and based upon a physical examination of the individual and a review of the patient's medical history. It is often made in infants after a heart problem is diagnosed. In children without significant heart problems, the possibility of a diagnosis may first be raised by preschool teachers or by other medical professionals such as plastic surgeons and speech therapists. These medical professionals may be

QUESTIONS TO ASK YOUR DOCTOR

- Please explain the meaning of the term “22q11 syndrome.”
- What is the pattern of inheritance of 22q11 syndrome?
- What are the symptoms associated with 22q11 syndrome in children?
- Are there organizations that provide support for parents who have children with 22q11 syndrome?

seeing the child for one of the features of 22q11.2 deletion syndrome and may be the first ones to become suspicious about the diagnosis. In rare cases, the diagnosis is made in a parent after they have had an affected child.

While a diagnosis can be made based upon physical examination and medical history, the diagnosis is now confirmed by a DNA test.

Sometimes the 22q11 deletion is large enough that it can be seen during a karyotype analysis. A karyotype is a microscopic analysis of an individual's chromosomes. However, many 22q11 deletions are too small to be seen by microscopic examination, and another specific technique called fluorescent in situ hybridization testing, or FISH testing, can determine whether genetic material is missing. A FISH test will be positive (detect a deletion) in over 95% of individuals with 22q11.2 deletion syndrome. A negative FISH test for 22q11.2 deletion syndrome means that no genetic material is missing from the critical region on chromosome 22. Research testing on these individuals usually reveals that up to 5% of individuals with 22q11.2 deletion syndrome will have a smaller deletion that is not picked up by the routine FISH test.

Prenatal testing (testing during pregnancy) for 22q11.2 deletion syndrome is possible using the FISH test on DNA sample obtained by chorionic villus sampling (CVS) or by amniocentesis. Chorionic villus sampling is a prenatal test that is usually done at 10–12 weeks of pregnancy and involves removing a small amount of tissue from the placenta. Amniocentesis is a prenatal test that is usually performed at 16–18 weeks of pregnancy and involves removing a small amount of the amniotic fluid that surrounds the fetus. DNA is obtained from these samples and tested to see if the deletion responsible for 22q11.2 deletion syndrome is present. While prenatal testing is possible, it is not routinely performed. Typically, the test is done only if there is a family

history of 22q11.2 deletion syndrome or if a congenital heart defect has been seen on a sonogram (ultrasound).

A sonogram uses sound waves to provide an image of a fetus. During the second trimester of pregnancy, it becomes possible to evaluate the fetal heart. If a heart defect is detected, DNA testing may be offered to the parents (along with other tests) to determine the cause of the heart defect. Unfortunately, congenital heart defects are common and there are many other syndromes that also cause congenital heart defects.

Treatment and management

Because of the incredible variability seen in 22q11.2 deletion syndrome, there is no one plan of treatment for all affected individuals. The treatment and management of an individual with 22q11.2 deletion syndrome depends on his or her age and symptoms. Because 22q11.2 deletion syndrome is a multisystem disorder, it is important to have multiple evaluations. Individuals with 22q11.2 deletion syndrome may see geneticists, plastic surgeons, immunologists, cardiologists, rheumatologists, endocrinologists, ophthalmologists, neurosurgeons, pediatricians, audiologists, and specialists in feeding, speech, and child development.

It is important that all individuals with 22q11.2 deletion syndrome have a cardiac evaluation by a cardiologist. An evaluation may include special tests such as a chest x-ray, electrocardiogram, and echocardiogram (ultrasound of the heart). Some cardiac defects do not require treatment, and others may require surgery.

Because of the wide variety of cleft palate and velopharyngeal problems, all individuals with 22q11.2 deletion syndrome should be evaluated by a cleft palate team. Cleft palate teams may include a plastic surgeon, ENT (ear, nose, and throat) specialist, genetic counselor and other staff. Because of the effect of cleft palate abnormalities on speech, all children with deletion 22q11 should have a speech evaluation and speech therapy if necessary. A referral to a feeding specialist may also be helpful if there is a cleft problem or other medical problem that interferes with feeding.

Because of the possibility and serious nature of immune problems, individuals with 22q11.2 deletion syndrome should have an immune evaluation. This can be done by an immunologist and usually requires blood tests to check immune function.

Individuals with 22q11.2 deletion syndrome should also have an endocrinology examination to check the function of their thyroid, parathyroid, and pituitary glands. They may also see an endocrinologist if they are having growth problems.

Neurologists can help with issues such as seizures and other neurology problems. Psychiatrists can help with psychiatric illness and problems arising from having a chronic illness.

Individuals with 22q11.2 deletion syndrome should be seen by a geneticist to confirm the diagnosis and to discuss issues such as the inheritance of 22q11.2 deletion syndrome, the recurrence risks and the availability of pre-natal diagnosis. Geneticists can also help arrange the necessary medical consults.

Prognosis

The prognosis for individuals with 22q11.2 deletion syndrome is highly dependent on the medical complications of the specific individual. Because this is such a variable syndrome, it is impossible to give one prognosis. The cardiac defects associated with 22q11.2 deletion syndrome are a major variable in determining prognosis. Those with serious heart defects have a guarded prognosis. Individuals with 22q11.2 deletion syndrome with minor or treatable cardiac defects have a good prognosis. Good medical care and treatment of problems allows most individuals with 22q11.2 deletion syndrome to have a normal lifespan.

While the physical features and medical complications of 22q11.2 deletion syndrome can affect prognosis, the degree of intellectual and psychological disability can also have an effect. Those individuals with normal IQ and no mental illness have a good prognosis. Those with learning disabilities can benefit from specific educational interventions. Individuals with developmental delay need more help but can do well in sheltered environments. Individuals with mental illness may or may not do well. Some individuals benefit from psychiatric counseling and medication.

The range of abilities among individuals with 22q11.2 deletion syndrome is very wide, and the ultimate functioning of an individual is dependent on his or her abilities.

22q13 deletion syndrome

Definition

The 22q13 deletion syndrome is a microdeletion syndrome. It results from missing a small segment of genetic material on the end of the long arm (q) of chromosome 22. The condition was first described in the literature in the 1980s. Individuals with the condition have a variety of features. The most common features are developmental delay, delayed or absent speech, and weak muscles (also known as hypotonia or low muscle tone).

Description

Phelan-McDermid syndrome, also known as 22q12 deletion syndrome, is named after the doctors known for their research on this syndrome. In the past, the condition had been referred to by both names, but Phelan-McDermid syndrome is now the preferred name.

Phelan-McDermid syndrome results from a chromosome difference. People typically have 23 pairs of chromosomes. The first 22 chromosomes are called autosomes and are numbered one to 22. The last pair are the sex chromosomes, identified as X and Y. Each chromosome has a long part (q) and a short part (p). Packed in the chromosomes are genes, which are important because they determine how a person grows, develops, and functions. They also determine physical features of an individual, such as eye color and the shape of a person's face. When a person's genes are missing or not working properly, the result can be health problems, learning difficulties, and/or physical differences.

Individuals with 22q13 deletion syndrome are missing part of a chromosome. The syndrome's name provides the location of the missing part. It is on the long arm of chromosome 22 at the very end (location q13). Since the 22q13 region contains genes, people missing this region do not have all the proper instructions for development. As a result, they have similar learning difficulties, physical differences, and behavior problems.

Genetic profile

The 22q13 deletion syndrome is caused by an absence of genetic material on chromosome 22. There are several different ways for an individual to have a deletion of 22q13. Approximately 80% of individuals with Phelan-McDermid syndrome have either a terminal deletion of 22q13 or an interstitial deletion of 22q13. A terminal deletion of 22q13 occurs when the entire short arm of chromosome 22 after the regions of 22q13 is missing. An interstitial deletion of 22q13 occurs when a small area within the 22q13 region is deleted but the rest of the long arm is still present. Approximately 20% of people with Phelan-McDermid syndrome have deletions of 22q13 due to a chromosome rearrangement such as an unbalanced chromosome translocation or other type of chromosome rearrangement. A very small number of people have Phelan-McDermid syndrome due to a disruption or mutation within the *SHANK3* gene.

Three genes have been identified as involved in causing the features of Phelan-McDermid syndrome—*SHANK3*, *ACR*, and *RABL2B*. The *SHANK3* gene is the critical gene for the diagnosis of Phelan-McDermid

KEY TERMS

Microdeletion syndrome—A syndrome caused by the deletion of a very small amount of chromosomal material.

Prenatal diagnosis—The use of a medical test to determine if an unborn baby has the genetic condition.

syndrome. Virtually all individuals with Phelan-McDermid syndrome have a deletion of this gene, or other genetic change within the *SHANK3* gene, that disrupts the function of this gene. The *SHANK3* gene codes for the SHANK3 protein, which is found in the brain, heart, kidney and other organs. The SHANK3 protein's most important role is in the brain. Researchers believe an absence of the SHANK3 protein causes the neurological features of intellectual disability and speech delay. In addition, mutations in the *SHANK3* have been seen in individuals with autism.

When a person is diagnosed with 22q13 deletion syndrome, it is usually the first time it has been seen in the family. For most parents, the chance of having a second child with the condition is low. In some families, however, an increased risk exists for having a second child with the syndrome. In these families, a parent usually has a balanced translocation, which means that parent has the correct amount of chromosome material, but the material is rearranged. The rearrangement usually does not cause problems in the parent. However, when the parent has a child, the child may receive extra or missing pieces of chromosome material.

If a parent has a balanced translocation involving the 22q13 region, he or she may be at risk of having multiple children with the syndrome. Therefore, parents of a child with 22q13 deletion syndrome should consider genetic testing for balanced translocations. Parents who are found to carry a translocation may decide to pursue prenatal diagnosis for future pregnancies. If an individual with 22q13 deletion syndrome had children, he or she would have a 50% chance of having a child with the condition and a 50% chance of having a child without the condition. As of the past few years, there were no known cases of an individual with the condition having children.

Demographics

The 22q13 deletion syndrome affects males, females, and all ethnicities. It is not known how many people have

22q13 deletion syndrome. The syndrome is considered rare, and researchers believe it is often underdiagnosed.

Signs and symptoms

Individuals with 22q13 deletion syndrome have a variety of symptoms. In addition, the severity of each feature ranges from mild to severe. Therefore, two people with the syndrome may have very different characteristics. The characteristics most commonly seen are developmental delay, low muscle tone, speech difficulties (lack of speech or absence of speech), and advanced growth. Many individuals also have behavior differences, including autistic-like behavior and/or excessive chewing.

In addition, some children learn a specific skill and lose it. The medical term for the loss of a skill is regression. When children with the condition lose a skill, it is usually in the area of speech. Other characteristics that are not as common in the syndrome but have been reported include drooping eyelids, large head, webbing between the second and third toes, large hands, lack of sweat, seizures, flaky toenails, and differently shaped ears, skull, and/or forehead.

Diagnosis

The diagnosis is made by determining the 22q13 chromosome region is missing. Sometimes the deletion of chromosome 22 can be seen by a routine chromosome analysis. Often, however, the deletion is difficult to see and other molecular genetic testing methodologies are used. While only one type of testing used to be the standard for diagnosis, new genetic testing methods are now preferred. The molecular genetic tests that are used to diagnose Phelan-McDermid syndrome include genomic microarray technologies, such as array-based comparative genomic hybridization (aCGH) or chromosomal microarray analysis (CMA) and targeted deletion analysis, such as fluorescence in situ hybridization (FISH) or multiplex ligation-dependent probe amplification (MLPA). The genomic microarray technologies look for copy number variants (CNVs), and can detect the 22q13.3 deletion. The targeted deletion analysis tests detect missing (deleted) or extra (duplicated) chromosome segments.

Recently, several suggestions regarding testing for the condition have been presented in the literature. One suggestion was that physicians should consider testing babies with an unknown cause of weak muscles at birth. Physicians should also test individuals with severe speech delay and autistic-like behavior or people with developmental delay, absent or delayed speech, and physical differences.

Treatment and management

Treatment for 22q13 varies depending on the presenting symptoms and physical differences. Individuals may see a variety of specialists, including geneticists, psychologists, and neurologists. Most people with the syndrome receive speech, occupational, and/or physical therapy. Each type of therapy helps with specific features of the syndrome. For example, speech therapy can help improve communication; occupational therapy can assist in developing life skills; physical therapy can help strengthen muscles.

Support groups and resources are available for individuals with 22q13 deletion syndrome and their families. Information can be obtained through the Phelan-McDermid Deletion Syndrome Foundation.

Prognosis

In general, most individuals with 22q13 deletion syndrome need help and supervision all of their lives. However, the specific prognosis varies with each person depending on his or her specific characteristics. For example, an individual with mild intellectual deficits and a few physical differences would be expected to have a better prognosis than a person with severe intellectual disability, no speech, and behavior problems. Also, some individuals will have regression or loss of a specific skill, especially in the area of speech. It is not possible to determine which people will lose skills.

3D organoid biosystems

Definition

A 3D organoid biosystem is a three-dimensional (3D) group of cells grown outside of the body that mimics a human organ (organoid). Organoids are grown from cells derived from human stem cells or tissue from biopsy samples. Stem cells are undifferentiated cells from an adult or embryo that can develop into any cell of the body and can make copies of themselves indefinitely. They are used in research, drug discovery, vaccine development, and medical treatment and may one day be used for organ transplants.

Description

The word “organoid” means “organ-like.” Organoids have some of the functions of a real organ, but they are as small as the size of a pea. For example, a brain organoid has nerve cells (neurons) that can communicate with each other. A brain organoid also has different regions that are similar to those of the brain. Although organoids can currently be created that resemble some aspects of organs, they are not equivalent to a fully functioning organ. For example, intestine organoids have a structure that is similar to the lining of the intestine, but they are not as complex as the intestinal tract.

Organoids have three main characteristics:

1. They are 3D mini-organs made up of several types of cells.
2. They have the complexity and organization of an organ.
3. They have some of the functionality of an organ.

The limitations of using organoids are:

KEY TERMS

Biopsy—The examination of a piece of tissue taken from the body. It is often done when there is a tumor or other abnormality.

Cell—Building blocks that provide structure to the body and perform all of the functions of the body. Cells contain genetic information and can copy themselves. There are many different types of cells in the body.

Embryonic stem cells—Cells that are derived from the early human embryo that can transform into any different type of cell and can make copies of themselves indefinitely.

Induced pluripotent stem cells—Adult cells that are reprogrammed so that they can develop into all types of cells of the body and can make copies of themselves indefinitely.

Organ—An organ is a group of cells that form a structure that has a specific function. For example, the heart, stomach, or brain.

Stem cells—Cells that can transform into any different type of cell and can make copies of themselves indefinitely.

Tissue—Living material that is made up of cells that have a common function. The four types of tissue are connective, epithelial (skin), muscle, and nervous tissue.

- They do not contain all of the types of cells found in a real organ, so they do not completely represent an organ.
- It can be hard for researchers to recreate a specific disease in an organoid.
- They do not have all of the functionality of an organ.
- They can take years to develop.

Organoid Uses

Human organoids are currently used in research to develop drugs and study disease, body functions, and development. For example, they have been used to study things like intestinal function, infectious and genetic diseases. In the future, they may be used to create organs that can be used in transplants.

Researchers can study genetic diseases by growing organoids from cells that have gene mutations. This can help them see how different mutations cause certain genetic conditions. For example, researchers used intestinal organoids to discover a gene mutation that prevents the intestines from developing properly. They found that

they were unable to create healthy intestinal organoids when they used tissue from six patients with an intestinal disorder, and they discovered that the six patients had a mutation in the same gene that was involved in the development of the intestines.

Organoid research can also be used to study how microbes like viruses and bacteria infect human cells. For example, researchers have used lung organoids the size of a lentil to study the impact of COVID-19 on the lungs. They also have used organoids to discover how SARS-CoV-2, the virus that causes COVID-19, can infect different types of organoids. This work allowed them to demonstrate how COVID-19 attacks multiple organs and not just the lungs.

Organoids are used in the development of medications. They allow researchers to see how well an organ responds to a drug candidate and whether the drug is toxic. Organoids make drug discovery easier, because they allow researchers to study many different types of drugs at the same time and to test on human organs earlier rather than testing them solely on animals. In the future, organoids made from a patient's stem cells could allow for the development of personalized medicine, customized for each individual patient.

Organoid Development

To make organoids, researchers take stem cells or cells from tissue and add them to a medium in which they can grow, like a protein material. They then provide them with an environment that will promote growth by adding specific nutrients and chemicals. Often, these components must be added in a particular order and way. The growing conditions also help the stem cells multiply and develop into the different cells that are part of the organ that is being mimicked. The cells need to organize themselves in the structures found in the organ. For example, the cells in kidney organoids organize themselves into small tubes (tubules) like those in real kidneys. It is difficult to create organoids, and it can take many years to figure out the proper growing conditions. Once the growing conditions have been worked out and provided to the cells, the cells can develop into organoids on their own.

3D printing of Organoids

3D printing promises to help speed the development process, reduce the costs, and increase the size of organoids. It also may be possible to 3D-print organs for transplantation. Eventually, it could be possible to take cells from a patient and use them to create the tissue or organ that they need, which could eliminate the risk of rejection found by using donor organs and could decrease the difficulty and cost of finding a suitable donor.

Organoids can be created by special 3D printers that use ink made of live cells or biological materials that can provide support to the cells. The printer converts a computer model into a printed shape. Harvard University professor Jennifer Lewis is researching using 3D printing to create heart organoids. She used a 3D printer to create sections of heart tissue and then added stem cells, which were stimulated to form heart cells. Eventually, all of the cells fused together and began to beat together like a heart. Researchers hope to be able to 3D print the entire heart for use in transplants.

3-M syndrome

Definition

3-M syndrome is a rare autosomal recessive disorder characterized by dysmorphic features such as short stature (dwarfism), skeletal abnormalities, and growth retardation without abnormal cognitive function. It was named for the researchers who first identified it (Miller, McKusick, and Malvaux). This syndrome may also be referred to as 3-MSBN, dolichospondylic dysplasia, or Le Merrer syndrome.

Description

3-M syndrome is an intrauterine growth malformation syndrome caused by mutation of a gene coding for proteins largely associated with the checks and balances of other proteins. Individuals with the syndrome display a slow growth rate and symptoms limited mostly to the skeletal system. The types of mutations seen throughout 3-M syndrome research include, but are not limited to, substitutions of one amino acid for another sometime during the coding process (DNA replication, transcription, or translation) of the cullin 7 protein. Other mutations of the gene result in a cullin 7 protein that is abnormally short and nonfunctional.

Genetic profile

Gene mutations in 3-M syndrome occur in the CUL7, OBSL1, or CCDC8 genes. The CUL7 gene has a cytogenic location 6p21.1, meaning that it is located on the short arm of chromosome 6 at position 21.1. It has a molecular location on chromosome 6 from base pairs 43,037,616 to 43,053,949. CUL7, also known as cullin 7 for the protein it codes for, appears to be the major gene responsible for causing 3-M syndrome. It is seen in roughly 77% of cases, while OBSL1 mutations account for roughly 16% and CCDC8 mutations account for roughly 7%. Research has identified at least 25 mutations in the CUL7 gene in individuals previously diagnosed with 3-M syndrome.

In addition to the 25 recorded mutations that have an outcome of 3-M syndrome, one other variant has also been discovered. This variant, found within a small population of individuals in the Yakut region of Siberia, has recently been categorized as a heterozygous autosomal recessive mutation. The mutation has been mapped out to show that the CUL7 gene in this group genetically causes the substitution of a stop codon for one glutamine. The result of this exchange is an early stop of the coding of the rest of the gene, leading to incorrect coding for—and ultimately incorrect functioning of—the protein. Due to its heterogeneous nature, the Yakut variant of 3-M syndrome results in more severe physiological abnormalities. Other case studies around the world have revealed a homozygous deletion in exon 18, which causes a frameshift mutation of the CUL7 gene and leads to the disorder.

The CUL7 gene plays a role in the ubiquitin-proteasome system, which breaks down and disposes of unwanted or malformed proteins. This system also plays a role in the regulation of the levels of proteins involved in the timing of cell division and growth. CUL7 specifically codes for the protein cullin 7, which helps to assemble the E3 ubiquitin ligase complex. Cullin 7 works

KEY TERMS

Aneurysm—An abnormal blood-filled bulge in a blood vessel, and especially an artery, resulting from weakening (as from disease) of the vessel wall.

Asphyxia—The state of not being able to breathe.

Cognitive—Of, relating to, or involving conscious mental activities (such as thinking, understanding, learning, and remembering).

Cytogenic—Pertaining to the production of cells.

Dwarfism—The condition of stunted growth.

Dysmorphic—An anatomical malformation.

Growth Hormone—A vertebrate polypeptide hormone that is secreted by the anterior lobe of the pituitary gland and regulates growth.

Heterozygous mutation—A mutation in which both copies of a gene are mutated.

Intrauterine—Of, situated in, used in, or occurring within the uterus.

Ubiquitin-proteasome system—A multicomponent system that identifies and degrades unwanted proteins in the cytoplasm of all cells. It is involved in cell growth and differentiation, DNA replication and repair, apoptosis, and stress and immune responses.

within the complex alongside other proteins to tag and then dispose of unwanted proteins. When the gene is coded incorrectly, such as in the case of 3-M syndrome, the body cannot manage proteins correctly, which results in the malformation of the human body as a whole. Research, however, is lacking studies that outline the relationship between cullin 7 and the signs and symptoms of the disorder, specifically the connection between the protein and the skeletal system. Despite the lack of research in this area, however, it is known that these gene abnormalities only appear in 3-M syndrome.

Demographics

Although 3-M syndrome's prevalence is unknown, it is estimated that approximately 100 individuals have been diagnosed since the first case in 1975, found by Miller. Laws of Mendelian genetics and the literature have shown that each sibling of an individual with 3-M syndrome has a 25% chance of having the genetic mutation, a 50% chance of being a carrier, and a 25% chance of neither. Along with developing most of the identified physical and radiological characteristics of 3-M

syndrome, people with this form of the genetic disorder have a high prevalence of respiratory problems leading to death in infancy. This is more highly associated with the Yakut short stature syndrome variant seen in Siberia.

Signs and symptoms

Individuals with 3-M syndrome show signs of growth retardation in-utero, although they typically have a full or almost full gestation period. This slow growth rate occurs after birth as well and continues throughout childhood and adolescence until skeletal maturation occurs when growth ceases, as it does in all humans. Individuals with this genetic disturbance initially are low on the weight and length charts at birth, typically the first sign of the disorder. One study that compared birth weight and birth length of 4 individuals with 3-M syndrome showed an average of 3.28 standard deviation score (SDS) under the normal birth weight and an average of 5.14 SDS under the normal birth length. Clinical studies show that as development progresses, characteristic facies, radiological findings, and a lack of neurological and cognitive findings are noted as the major signs and symptoms of the disorder.

Characteristic facies typically observed in 3-M syndrome include the following:

- triangular face
- broad forehead
- frontal bossing
- short stature
- nostrils that are rotated into an anterior position
- disproportionate head-to-body ratio
- hypoplastic midface

The literature suggests that individuals with 3-M syndrome show abnormal radiological features including, but not limited to, the following:

- elongated and narrow vertebral bodies, particularly in the lumbar region
- broad thorax with slender and horizontal ribs
- flared metaphyses
- enlarged calcaneus
- slender, long bones
- Sprengel's deformity of the scapulae
- anterior wedging of thoracic vertebral bodies
- irregular upper and lower endplates
- thoracic kyphoscoliosis
- spina bifida occulta
- small pelvic bones
- small iliac wings
- slightly delayed bone age

QUESTIONS TO ASK YOUR DOCTOR

- What reproductive complications may I encounter during life, and how can this be rectified?
- Am I a candidate for rhGH treatment?
- How should I be evaluated for possible aneurysms and at what time in my life?
- Can my future spouse be tested for being a carrier for this gene to determine the chances of having a child with the syndrome?
- What options for treatment are available and applicable to me and my condition?
- Are there support groups for people who have similar syndromes?
- What are my limitations of activities of daily living? How can I improve my condition to decrease any limitations?

Diagnosis

A diagnosis of 3-M syndrome is suggested in children with low birth weight, severe growth retardation, characteristic facies, and characteristic radiological findings without any change to the abdomen, cardiovascular system, and/or nervous system. The signs and symptoms of the disorder have a high correlation to the diagnosis of the condition, although a genetic profiling test such as sequence analysis or deletion/duplication analysis is most important in the diagnosis of an individual thought to have the disorder. Genetic testing is helpful in differentiating 3-M syndrome from other genetic abnormalities showing dwarfism, such as Floating-Harbor syndrome, achondroplasia, spondyloepiphyseal dysplasia, diastrophic dysplasia, Russell-Silver syndrome, Dubowitz syndrome, Mulibrey nanism, and fetal alcohol syndrome. Bloodwork may also be a good diagnostic tool, but there is an inconsistency in cases with a deficiency in growth hormone.

Treatment and management

Individuals diagnosed with 3-M syndrome are screened and evaluated throughout life, though more so during skeletal immaturity. To evaluate the extent of the disease in an individual, a physical examination is performed. Joint mobility is evaluated to measure and control the development of arthritis. The level of arthritis noted may yield management as seen fit by orthopedic physicians or another healthcare physician. Individuals

are often screened throughout life to prevent brain aneurysms. In addition to physical examination, surveillance of growth every 6 to 12 months on standard growth charts, with special attention to growth rate, is recommended. A blood test for a growth hormone deficiency may also be recommended. If a blood test concludes a deficiency in growth hormone, the use of recombinant human GH (rhGH) for the treatment of short stature associated with 3-M syndrome may be used, as it has been documented in literature. However, significant individual variation is reported in relation to GH response. This variation may be accounted for by the variable response to GH based on the genotype, with a better response noted in patients that have a CCDC8 mutation as compared to an OBSL1 mutation.

In addition to physical examination and screening, males with 3-M syndrome should be referred for endocrinologic evaluation at puberty regarding gonad function.

Although treatment of 3-M syndrome is inconsistent, management of the disorder is positive. Adaptive aids for activities of daily living such as bathing, dressing, and driving vehicles have been established. Surgical bone lengthening may also be an option.

Genetic counseling may also be rendered, because there is a correlation between an individual with 3-M syndrome and future siblings developing the disorder. Prenatal screening can be done via ultrasound by checking for slow growth of all long bones. Carrier testing and prenatal testing may be administered for families with previously diagnosed family members as well.

Prognosis

The prognosis of individuals diagnosed with 3-M syndrome is good, due to the lack of signs and symptoms seen in other systems of the body aside from the skeletal system. The literature shows a small chance of early death occurring in infancy due to respiratory malfunctions associated with protein malformation, more specifically in the Yakut short stature syndrome variant. One study showed that of 43 diagnosed individuals in 37 Yakut families, approximately 42% of them had severe asphyxia and respiratory distress at birth associated with poor development of the cartilaginous lamina of the bronchi, leading to death.

3-Methylglutaconic aciduria type 2

Definition

3-methylglutaconic aciduria type 2 (MGCA2) is a rare and serious X-linked metabolic and neuromuscular genetic disorder affecting males. It is one of five subtypes of 3-methylglutaconic aciduria (MGA), a group of disorders that affect the body's ability to make energy in the mitochondria of cells. As a result of this deficiency, two organic molecules called 3-methylglutaconic acid and 3-methylglutaric acid build up in the body and can be detected in the patient's urine. The disorder is also known as Barth syndrome, after the Dutch pediatrician who first reported on it in 1981 and demonstrated that it is an inherited disorder. It is also called BTHS and cardiomyopathy-neutropenia syndrome.

3-methylglutaconic aciduria type 2 is caused by a mutation in the tafazzin gene (referred to as *TAZ*) on the long arm of the X chromosome at Xq28. This mutation results in adverse effects on multiple systems of the body, including the cardiac and skeletal muscle systems. Severe infections and cardiac failure are common causes of death in individuals with 3-methylglutaconic aciduria type 2. There are over 160 different mutations of the *TAZ* gene that are known to cause 3-methylglutaconic aciduria type 2 as of 2015. The *TAZ* gene is also known as the *BTHS*, *CMD3A*, *EFE*, *G4.5*, or *LVNCX* gene.

Description

3-methylglutaconic aciduria type 2 was identified and described by Peter Barth (1932–) of the Netherlands in publications in 1981 and in 1983. Richard Kelley of Johns Hopkins University published an additional

description of the syndrome in 1991. The specific location of the gene on the X chromosome responsible for the disorder was identified in 1996.

Genetic profile

3-methylglutaconic aciduria type 2 is an X-linked recessive genetic condition that is usually transferred from mother to son. A mother who is a carrier of the syndrome will show no signs or symptoms of the disease. A female carrier has a 50% chance of giving birth to a son with 3-methylglutaconic aciduria type 2, while her daughters have a 50% chance of becoming carriers. Females with an X chromosome with a tafazzin mutation do not develop the syndrome as they have a second X chromosome with a normal tafazzin gene that is dominant over the recessive mutated tafazzin gene. All daughters of a male with 3-methylglutaconic aciduria type 2 will be carriers, but none of his sons.

Demographics

The prevalence rate of 3-methylglutaconic aciduria type 2 is estimated at between 1 in 300,000 to 1 in 400,000 male infant births and appears to occur in all ethnic groups. About 150 cases worldwide have been described in the medical literature. Fewer than ten new cases of the syndrome are identified each year in the United States. There are fewer than 500 individuals with 3-methylglutaconic aciduria type 2 listed on the registry of the Barth Syndrome Foundation.

3-methylglutaconic aciduria type 2 is listed as a rare disease by the Office of Rare Diseases (ORD) of the National Institutes of Health (NIH) in the United States, which means that the syndrome affects fewer than 200,000 people in the U.S. population. Orphanet, a database of rare diseases and orphan drugs developed by a consortium of European partners, defines a condition as rare if it affects 1 in 2,000 people. 3-methylglutaconic aciduria type 2 is considered a rare disease by Orphanet. It is possible, however, that the incidence of the syndrome may be underestimated. Male infants and children who die of acute dilated cardiomyopathy are often thought to have viral myocarditis and may not have been tested for 3-methylglutaconic aciduria type 2.

Signs and symptoms

There is considerable variability in degree and type of conditions associated with individuals with 3-methylglutaconic aciduria type 2. The defining characteristics of the disease include the following conditions:

- Weak heart muscle
- Abnormally low level of neutrophils
- Muscles having a cellular deficiency

KEY TERMS

Cardiolipin—A type of lipid (fatty substance) found almost exclusively in the inner mitochondrial membrane where it is essential for the optimal function of numerous enzymes involved in mitochondrial energy metabolism.

Endocardial fibroelastosis (EFE)—An abnormal thickening of the lining of the heart tissue due to a concentration of elastic collagen-like fibers.

Heart arrhythmia—An abnormal heart rhythm, in which the heartbeats may be too slow, too rapid, too irregular, or too early.

Learning disability—Refers generally to a group of disorders manifested by significant difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning, or math abilities.

Mitochondria (singular, mitochondrion)—Specific compartments within cells that act as the cells' power plants. Mitochondria make and supply energy to cells to carry out all of the cells' jobs.

Tafazzin—A protein involved in modifying the structure of cardiolipin. Tafazzin adds a molecule of linoleic acid to the cardiolipin molecule, which enables cardiolipin to perform its functions. The protein was named for a comic character in an Italian television show by its discoverers, a team of Italian researchers.

Tafazzin gene (TAZ)—A human gene located on the X chromosome that encodes tafazzin, a protein expressed at high levels in cardiac and skeletal muscle. Mutations in this gene have been associated with a number of disorders, including 3-methylglutaconic aciduria type 2 and dilated cardiomyopathy.

Individuals with 3-methylglutaconic aciduria type 2 typically develop a weak heart muscle usually associated with enlargement of the heart. In most affected individuals, there is poor muscle tone at birth, with signs of cardiomyopathy typically developing during the newborn period or within the first few months of life. The left ventricle of the heart is often thicker than normal due to a concentration of elastic collagen-like fibers in its lining, a condition known as endocardial fibroelastosis (EFE). The thickening of the left ventricle leads to a reduced ability to pump blood from the heart to the lungs, thus increasing the risk of heart failure.

Individuals with the syndrome also have an abnormally low level of neutrophils, a type of white blood cell

that is important in fighting bacterial infections. This condition, referred to as neutropenia, can result in mouth ulcers, fevers, bacterial pneumonia, and skin abscesses. Neutropenia can be as dangerous to children with 3-methylglutaconic aciduria type 2 as cardiomyopathy.

3-methylglutaconic aciduria type 2 also results in muscles having a cellular deficiency that limits their ability to produce energy. Persons with the syndrome, therefore, exhibit muscular weakness, particularly in the muscles closest to the center of the body, and increased fatigue during movement, resulting in exercise intolerance. The children may exhibit a waddling gait and reduced muscle mass.

During childhood, individuals with 3-methylglutaconic aciduria type 2 are usually underweight and below average in height. Birth weight may be normal or slightly reduced, but by two years of age, children with the syndrome are noticeably below normal for height with a proportional or even much lower weight even when adequately nourished. However, they often reach normal or low-normal height during the mid- to late-teenage years. Males with the syndrome often have characteristic facial features that include chubby cheeks, deep-set eyes, and prominent ears.

3-methylglutaconic aciduria type 2 has adverse effects on the functioning of the mitochondria of cells, which are the primary energy producers in cells. Individuals with 3-methylglutaconic aciduria type 2 have an increase in the organic acid 3-methylglutaconic acid, which results in abnormal functioning of the mitochondria. The mitochondria also cannot make adequate amounts of tetralinoleoyl-cardiolipin, an essential lipid necessary for normal mitochondrial structure and activity.

The major problems associated with 3-methylglutaconic aciduria type 2 are congestive heart failure, heart arrhythmia, severe bacterial infections, gross and/or fine motor developmental delays, delay in growth, exercise intolerance, and lack of stamina. The heart arrhythmia often results in sudden death. Other problems that individuals with Barth syndrome may develop include frequent diarrhea, osteoporosis, chronic headaches, extreme fatigue, and feeding problems. Body aches also occur, especially during puberty. Most affected children have normal intelligence but may exhibit mild to moderate learning disabilities, especially in the areas of spatial and computational reasoning.

Diagnosis

An early diagnosis of 3-methylglutaconic aciduria type 2 is critical for survival. Any child or adult who has one or more of the characteristics of the condition should be evaluated. Genetic testing involving DNA

sequence analysis or mutation scanning of the entire coding region of the tafazzin gene is recommended. The diagnostic tests include:

- Urinalysis
- Cardiolipin analysis of muscle, blood platelets, or cultured cells
- A complete blood count and differential, which includes the total number of white blood cells as well as specific types of white cells. All indicate the presence of various types of infections or diseases
- An echocardiogram to create a moving picture of the heart

A complete family history should also be obtained, with emphasis on identifying cases of cardiac disease, failure-to-thrive, and unexplained infant or sudden deaths.

Treatment and management

There is no known cure for 3-methylglutaconic aciduria type 2. Treatment is supportive and palliative, and regular medical care tailored to the individual patient is essential to manage symptoms and conditions associated with the syndrome. Symptoms are treated as they occur. Antibiotics are used to treat infections. Granulocyte colony stimulating factor, or GCSF, can stimulate white cell production by bone marrow to fight infections. Various types of medicines can be used to control heart problems.

Diet should be monitored to assure that affected children do not become deficient in calcium or other nutrients. Overfeeding to encourage growth may lead to chronic diarrhea and increased acidosis. Children with 3-methylglutaconic aciduria type 2 have a lower level of potassium in their muscles and may become potassium-depleted during bouts of diarrhea. However, if the children are given intravenous fluids containing potassium to counteract potassium depletion, they may develop hyperkalemia (abnormally high levels of potassium in the blood), which can cause death.

Prognosis

In the past, males with 3-methylglutaconic aciduria type 2 usually died of heart failure or infection by three years of age. However, with improved detection of the syndrome and monitoring and treatment of symptoms, the survival rate and lifespan of affected children is increasing. In many children (estimated at up to 75%) affected by the syndrome who have been studied through puberty, cardiac disease has improved substantially. In some cases, it has even been cured by the end of the puberty growth spurt. Improved treatment with cardiac drugs and heart transplantation has eliminated progressive cardiac disease in many children. Between 1985

QUESTIONS TO ASK YOUR DOCTOR

- Which symptoms and conditions do we need to watch for in our child?
- Is heart transplantation an option in our child's case?
- Which medical specialists should we consult for our child's specific condition?
- What organizations and support groups are available?
- Where can we obtain genetic counseling for possible future pregnancies?

and 2005, in the United States, only 10% of children with 3-methylglutaconic aciduria type 2 have died, compared to 70% of their older relatives who were born before the diagnosis of the syndrome in their family was made.

In spite of advances in medical care, however, males with 3-methylglutaconic aciduria type 2 have shortened lifespans; those who survive into adulthood usually die in their late forties. Peter Barth reported in 2005 that no known female carriers of the defective *TAZ* gene show symptoms of the syndrome, and that their lifespans do not differ from that of the general population.

Prevention

There is no known prevention for 3-methylglutaconic aciduria type 2. Based on family history and known cases in family members and ancestors, parents may seek genetic counseling to determine their risk of having a child with the syndrome. They may seek genetic testing to evaluate the *tafazzin* gene status to determine whether the mother is a carrier of 3-methylglutaconic aciduria type 2. Based on the results of genetic testing, parents may choose to adopt, become pregnant with an egg from an unaffected donor, prevent pregnancy, or terminate an affected fetus. Counseling may also help parents prepare for treatment and care of an affected infant after birth.

46,XX testicular disorder of sex development

Definition

46,XX testicular disorder of sex development occurs when the affected individual appears as a normal male but has female chromosomes. Two types of 46,XX

Disorders associated with multiple X or Y chromosome inheritance

Disorder	Chromosome affected	Karyotype	Incidence	Symptoms
Turner syndrome	X	45,X (monosomy)	1 in 2,000	Growth retardation Infertility Cardiovascular malformations Learning disabilities
Klinefelter syndrome	X	47,XXY (trisomy)	1 in 500–800	Taller than average Poor upper body strength; clumsiness Mild intention tremor (20–50%) Breast enlargement (33%) Decreased testosterone production Infertility
Triple X	X	47,XXX (trisomy)	1 in 1,000	Dyslexia (50%) Mild delays in motor, linguistic and emotional development Learning disabilities
XYY syndrome	Y	47,XYY	1 in 1,000	Slightly taller than average Taller than average Lack of coordination Acne Some infertility Learning disabilities (50%) Behavior problems, especially impulse control
XX male syndrome	Y	46,X,t(X,Y) (translocation of the SRY gene [90%] or other gene responsible for male sex determination)	1 in 20,000–25,000	Usually normal male physical features but may have ambiguous genitalia, hypospadias or undescended testes Infertility Shorter than average

Disorders associated with multiple X or Y chromosome inheritance (Gale)

testicular disorder of sex development can occur: those with detectable *SRY* gene and those without detectable *SRY*. *SRY* is the main genetic switch for determining that a developing embryo will become male.

Description

46,XX testicular disorder of sex development is a condition in which the sex chromosomes of an individual do not agree with the physical sex of the affected person. Normally, there are 46 chromosomes, or 23 pairs of chromosomes, in each cell. The first 22 pairs are the same in men and women. The last pair, the sex chromosomes, may be two X chromosomes in females (XX) or an X chromosome and a Y chromosome in males (XY).

In 46,XX testicular disorder of sex development, the person has female chromosomes but male physical features. The majority of individuals with 46,XX testicular disorder of sex development have the Y chromosome gene *SRY* attached to one of their X chromosomes. The rest of the individuals with 46,XX testicular disorder of sex development do not have *SRY* detectable in their cells. Hence, other genes on other chromosomes in the pathway for determining sex must be responsible for their male physical features.

Genetic profile

If the 46,XX testicular disorder of sex development caused by the gene *SRY*, a translocation between the X chromosome and Y chromosome causes the condition. A translocation occurs when part of one chromosome breaks off and switches places with part of another chromosome. In 46,XX testicular disorder of sex development, the tip of the Y chromosome that includes *SRY* is translocated to the X chromosome. As a result, an embryo that has XX chromosomes with a translocated *SRY* gene will develop the physical characteristics of a male. Typically, a piece of the Y chromosome in the pseudo autosomal region exchanges with the tip of the X chromosome. In 46,XX testicular disorder of sex development, this crossover includes the *SRY* portion of the Y.

In individuals with 46,XX testicular disorder of sex development who do not have an *SRY* gene detectable in their cells, the cause of the condition is not known. Scientists believe that one or more genes that are involved in the development of the sex of an embryo are mutated or altered and cause physical male characteristics in a chromosomally female person. These genes could be located on the X chromosome or on one of the 22 pairs of autosomes that males and females have in common.

Approximately 20% of XX males do not have a known cause and are SRY negative. It is thought that SRY is a switch point. This means that the protein made by SRY regulates the activity of one or more genes (likely on an autosomal chromosome) that contribute to sex development. Some research has identified an autosomal recessive and autosomal dominant inheritance for the XX male.

Demographics

46,XX testicular disorder of sex development occurs in approximately 1 in 20,000 to 1 in 25,000 individuals. The vast majority, about 90%, have SRY detectable in their cells. The remaining 10% are SRY negative, although some research indicates that up to 20% can be SRY negative. As there is no ethnic or racial differences in occurrence, 46,XX testicular disorder of sex development can occur in any ethnic background. It usually occurs as a sporadic event, not inherited from the person's mother or father. However, some examples of more than one affected family member have been reported.

Signs and symptoms

SRY positive 46,XX testicular disorder of sex development

Males with SRY positive 46,XX testicular disorder of sex development look like and identify as males. They have normal male physical features including normal male body and genitalia. All males with 46,XX testicular disorder of sex development are infertile (cannot have biological children) because they lack the other genes on the Y chromosome involved in sperm production. Men with 46,XX testicular disorder of sex development are usually shorter than an average male. This is because they do not have certain genes on the Y chromosome involved in height. A similar syndrome that affects males with two X chromosomes is Klinefelter syndrome. Those individuals with Klinefelter syndrome present with symptoms such as small testes and infertility.

SRY negative 46,XX testicular disorder of sex development

People with SRY negative 46,XX testicular disorder of sex development are more likely to be born with physical features that suggest a condition. Many have hypospadias, where the opening of the penis is not at the tip, but further down on the shaft. They may also have undescended testicles, where the testicles remain in the body and do not drop into the scrotal sac. Occasionally, an SRY negative affected male has some female structures such as the uterus and fallopian tubes. Men with SRY-negative 46,XX testicular disorder of sex development

KEY TERMS

Autosomes—Chromosome not involved in specifying sex.

Chromosome—A microscopic thread-like structure found within each cell of the body consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or in their shape and size (structure) may lead to physical or mental abnormalities.

Embryo—The earliest stage of development of a human infant, usually used to refer to the first eight weeks of pregnancy. The term “fetus” is used from roughly the third month of pregnancy until delivery.

Gene—A building block of inheritance containing the instructions for the production of a particular protein and consisting of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

can also have gynecomastia, or breast development during puberty. Furthermore, puberty may be delayed. As with SRY positive 46,XX testicular disorder of sex development, these men are infertile and shorter than average because they lack other Y-specific genes. The physical features can vary within a family, but most affected people are raised as males.

A small portion of people with SRY negative 46,XX testicular disorder of sex development are true hermaphrodites. This means they have both testicular and ovarian tissue in their gonads. They are usually born with ambiguous genitalia, a condition where the genitals of the baby have both male and female characteristics. Individuals with 46,XX testicular disorder of sex development and true hermaphrodites can occur in the same family, suggesting there is a common genetic cause for both. Research indicates that 15% of 46XX true hermaphrodites have the SRY gene.

Diagnosis

For people with 46,XX testicular disorder of sex development who have ambiguous genitalia, hypospadias, and/or undescended testicles, the diagnosis is suspected at birth. For males with 46,XX testicular disorder of sex development and normal male features, the diagnosis can be suspected during puberty when breast development occurs. Many men do not know they have 46,XX testicular disorder of sex development until they try to

QUESTIONS TO ASK YOUR DOCTOR

- What are the risks and benefits of testicular surgery?
- At what point should I discuss the condition with my child?
- When should testing for SRY be performed?
- What are the risks of this condition occurring in future pregnancies?

have their own children, are unable to do so, and are evaluated for infertility.

When the condition is suspected in a male, chromosome studies can be done on a small sample of tissue such as blood or skin. The results show normal sex chromosomes, or XX chromosomes. Further genetic testing is needed to determine if the *SRY* gene is present.

Some affected individuals have had *SRY* found in testicular tissue but not in their blood cells. This is called mosaicism. Most males only have their blood cells tested for *SRY* and not their testicular tissue. Therefore, some men who think they have *SRY* negative 46,XX testicular disorder of sex development may actually be mosaic and have *SRY* in their gonads.

46,XX testicular disorder of sex development can be detected before a baby is born. This occurs when a mother-to-be has prenatal testing done that shows female chromosomes but on ultrasound male genitals are found. Often the mother has had prenatal testing for a reason other than 46,XX testicular disorder of sex development, such as for an increased risk of fetal Down syndrome due to her age. Genetic testing, such as fluorescence in situ hybridization (FISH) and polymerase chain reaction (PCR), can detect the presence of the *SRY* gene through amniocentesis. An amniocentesis is a procedure in which a needle is inserted through the mother's abdomen into the sac of fluid surrounding the baby. Some of the fluid is removed and used to test for the presence of the *SRY* gene. Amniocentesis slightly increases the risk of miscarriage.

Treatment and management

For those with 46,XX testicular disorder of sex development with normal male genitals and testicles, no treatment is necessary. Affected males with hypospadias or undescended testicles may require one or more surgeries to correct the condition. If gynecomastia is severe enough, breast reduction surgery is

possible. The rare person with true hermaphroditism usually requires surgery to remove the gonads, as they can become cancerous.

Parents who learn their child has been diagnosed with 46,XX testicular disorder of sex development are encouraged to seek both emotional and educational support. Issues such as explaining the condition to their child when they are grown may be easier with the help of both medical professionals and other parents whose children are living with the condition.

Prognosis

The prognosis for males with 46,XX testicular disorder of sex development is excellent. Surgery can usually correct any physical problems. Men with 46,XX testicular disorder of sex development have normal intelligence and a normal lifespan. However, all affected men will be infertile.

Aarskog syndrome

Definition

Aarskog syndrome is an inherited disorder that causes a distinctive appearance of the face, skeleton, genitals, hands, and feet. First described in a Norwegian family in 1970 by the pediatrician Dagfinn Aarskog, the disorder has been recognized worldwide in most ethnic and racial groups. Because the responsible gene is located on the X chromosome, Aarskog syndrome occurs almost exclusively in males. It is not known exactly how many people have the rare disorder.

Description

Aarskog syndrome is among the genetic disorders with distinctive patterns of physical findings. Signs are present at birth, which allows for early identification. The facial appearance and findings in the skeletal system and genitals combine to make a recognizable pattern. The diagnosis is almost exclusively based on recognition of these findings. Aarskog syndrome is also called

Faciogenital dysplasia, Faciogenitodigital syndrome, and Aarskog-Scott syndrome.

Genetic profile

About one-fifth of cases of Aarskog syndrome are caused by mutations in the *FGD1* gene, located on the short arm of the X chromosome (Xp11.21). As many as 20 different mutations in the *FGD1* gene have been identified as responsible for the syndrome. In most cases the altered gene in affected male offspring is inherited from a carrier mother. Since men have a single X chromosome, mutations in the *FGD1* gene produce full expression. Girls and women who carry a mutation of the *FGD1* gene on one of their two X chromosomes are usually unaffected, but may have subtle facial differences and less height than other female members of the family. There may be other causes of Aarskog syndrome, but they have not yet been identified.

Female carriers have a 50% chance of transmitting the altered *FGD1* gene to offspring. Affected men are fully capable of reproduction. They transmit their single X chromosome to all daughters who, therefore, are

Aarskog syndrome: pedigree analysis chart (Gale)

carriers. Since men do not transmit their single X chromosome to sons, all sons of male carriers are unaffected.

The gene affected in Aarskog, called *FGDI*, codes for a Rho/Rac guanine exchange factor. While the gene product is complex and the details of its function are incompletely understood, it appears responsible for conveying messages within cells that influence their internal architecture and the activity of specific signal pathways. *FDGI* also belongs to a family of genes called zinc fingers that provide instructions for making certain proteins. The precise way in which mutations in *FGDI* produce changes in facial appearance and in the skeletal and genital systems is not completely known, but research published in 2012 showed that the protein helps to regulate bone development. Therefore, the alteration in this protein could lead to the physical signs in those affected by Aarskog syndrome.

Demographics

Only boys and men are affected with Aarskog syndrome, although female carriers may have subtle changes of the facial structures and be shorter than noncarrier sisters. There are no high-risk racial or ethnic groups.

Signs and symptoms

Signs and symptoms of Aarskog syndrome are present from birth. The facial appearance is distinctive and in most cases is enough to help a doctor diagnose the disease. Changes are present in the upper, middle, and lower portion of the face. Increased width of the forehead, growth of scalp hair into the middle of the forehead (widow's peak), increased space between the eyes (ocular hypertelorism), a downward slant to the eye openings, and drooping of the upper eyelids (ptosis) are the major features in the upper part of the face. A boy also may have a short nose with forward-directed nostrils and simply formed small ears that may protrude. The mouth is usually wide and the chin is small. As the face elongates in adult life, the forehead becomes more prominent and the increased space between the eyes becomes less apparent. The teeth may erupt more slowly than normal, and the child may have missing teeth and broad upper incisors.

A person with Aarskog syndrome often holds his hand in a distinctive position flexed at the joint between the hand and the fingers, and the joints may appear lax or loose. This hand posturing becomes more obvious when there is an attempt to spread the fingers. There may also be some mild webbing between the fingers. The fingers are short, and there is often only a single crease across the middle of the palm. The person's toes are also shorter than normal, and the foot is often bent

KEY TERMS

Rho/Rac guanine exchange factor—Member of a class of proteins that appear to convey signals important in the structure and biochemical activity of cells.

inward at its middle portion. All of the joints may be unusually loose. Excessive movement of the cervical spine may cause it to press on the spinal cord. In some cases, the sternum (breastbone) may appear sunken (pectus excavatum).

Changes in the appearance of the genitals may also be helpful in diagnosis. At birth, one or both testes may remain in the abdomen area, rather than descending into the scrotal sac as they should. The scrotum tends to surround the penis giving a so-called "shawl scrotum" appearance. Hernias may appear in the genital and umbilical regions. In childhood and adulthood, the boy's or man's height is generally less than the height of unaffected brothers.

Although most affected males have normal intellectual function, some individuals have mild impairments. There does not appear to be any particular association with behavioral problems, although there are rare reports of them. However, attention deficit occurs among some affected boys with learning difficulties.

Diagnosis

Diagnosis of Aarskog syndrome is made based on clinical findings, primarily analysis of the family history and characteristic facial, skeletal, and genital findings. There are no specific laboratory or imaging tests that help doctors diagnose the syndrome. When necessary, the diagnosis can be confirmed by finding a mutation in the *FGDI* gene.

Families with a known history of Aarskog syndrome could consider prenatal diagnosis through ultrasound examination of the unborn child's face, hands and feet, or by testing for the *FGDI* gene. However, this is not generally sought since the condition is not considered medically severe.

Few other conditions are confused with Aarskog syndrome. Noonan syndrome, another single gene disorder that has symptoms of short stature, ocular hypertelorism, downslanting eye openings, and depression of the lower chest, poses the greatest diagnostic confusion. Patients with Noonan syndrome often have wide necks and heart defects, which is helpful in distinguishing them

QUESTIONS TO ASK YOUR DOCTOR

- How definite is the diagnosis?
- Is surgery in the umbilical or groin region recommended?
- What testing should my child have to be certain that developmental milestones are reached?
- At what point do you recommend testing for attention deficit disorder?

from patients with Aarskog syndrome. The disorder also can be confused with pseudohypoparathyroidism and Robinow's syndrome.

It may be more difficult to diagnose Aarskog syndrome in an older patient because facial symptoms are less obvious and scrotum is obscured by pubic hair.

As in many disorders, there is a range of severity of the clinical appearance even within the same family. In these cases, examination of several affected family members and attention to family history may be helpful.

Treatment and management

Since there are no major malformations or major mental disabilities in Aarskog syndrome, the diagnosis may be reassuring. Developmental milestones and school progress should be monitored, as there may be impairment of intellectual function in some individuals. Some children are treated with growth hormone therapy.

The X-linked inheritance pattern should be described to the family.

Prognosis

Short-term and long-term prognosis is favorable. Life threatening malformations or other health concerns rarely occur. Special educational attention may be necessary for those with learning difficulties. A few affected individuals have spinal cord compression, usually in the neck, causing pain or injury to peripheral nerves, and may need neurosurgery. Hernias in the umbilical and groin areas may be surgically repaired.

Abetalipoproteinemia

Definition

Abetalipoproteinemia (ABL) is a rare inherited disorder characterized by difficulty in absorbing fat during digestion. The result is absence of betalipoproteins in the blood, abnormally shaped red blood cells, and deficiencies of vitamins A, E, and K. Symptoms include intestinal, neurological, muscular, skeletal, and ocular problems, along with anemia and prolonged bleeding in some cases.

Description

An unusual sign first described in ABL is the presence of star-shaped red blood cells, which were dubbed "acanthocytes" (literally, *thorny cells*). Thus, ABL is also known by the name acanthocytosis. Less commonly, ABL may be referred to as Bassen-Kornzweig syndrome.

The underlying problem in ABL is a difficulty in absorbing fats (lipids) in the intestine. Most people with ABL first develop chronic digestive problems, and then progress to neurological, muscular, skeletal, and ocular disease. Disorders of the blood may also be present. Severe vitamin deficiency causes many of the symptoms in ABL. Treatments include restricting fat intake in the diet and vitamin supplementation. Even with early diagnosis and treatment, ABL is progressive and cannot be cured.

Fats are important components of a normal diet. Their processing, transport, and use by the body are critical to normal functioning. Lipids bind to protein (lipoprotein) so they can be absorbed in the intestine, transferred through the blood, and taken up by cells and tissues throughout the body. There are many different lipoprotein complexes in the body. One group, the betalipoproteins, must combine with another protein, microsomal triglyceride transfer protein (MTP). ABL is caused by abnormalities in the gene that codes for MTP. When MTP is nonfunctional or missing, then betalipoproteins will also be decreased or absent. The *MTP* gene has been localized to chromosome 4.

ABL is an autosomal recessive genetic disorder. This means that both copies of the *MTP* gene are abnormal in a person affected with the disorder. Since all genes are present at conception, a person cannot “acquire” ABL. Each parent of an affected child carries the abnormal *MTP* gene but also has a normally functioning gene of that pair. Enough functional MTP is produced by the normal gene so that the parent is unaffected (carrier). When both parents are carriers of the same recessive gene, there is a one in four chance in each pregnancy that they will have an affected child.

Demographics

ABL is rare; the true incidence of the disorder is unknown. Prior to the description of ABL in 1950, it is believed that people with ABL were diagnosed as having either Friedreich ataxia (a more common form of hereditary ataxia) or some other neurologic disorder. Misdiagnosis may still occur if all of the symptoms are not present or if they do not occur in a typical fashion. Most of the reported cases of ABL have been in the Jewish population, but individuals from other ethnic backgrounds have been described as well. As many as one-third of people with ABL have had genetically related (consanguineous) parents. Higher rates of consanguinity are often seen in rare autosomal recessive disorders.

Signs and symptoms

Too much fat left unabsorbed in the intestine results in the symptoms that are often noticed first in ABL, such as chronic diarrhea, loss of appetite, vomiting, slow weight gain, and slow growth due to reduced uptake of nutrients.

Various lipids, such as cholesterol and its components, are important in the development and normal functioning of nerve and muscle cells. Decreased lipid levels in the bloodstream, and thus elsewhere in the body, are partly responsible for the neuromuscular and ocular problems encountered in ABL. Neurological symptoms

KEY TERMS

Acanthocytosis—The presence of acanthocytes in the blood. Acanthocytes are red blood cells that have the appearance of thorns on their outer surface.

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Chylomicron—A type of lipoprotein made in the small intestine and used for transporting fats to other tissues in the body. MTP is necessary for the production of chylomicrons.

Clubfoot—Abnormal permanent bending of the ankle and foot. Also called talipes equinovarus.

Consanguinity—A mating between two people who are related to one another by blood.

Lipoprotein—A lipid and protein chemically bound together, which aids in transfer of the lipid in and out of cells, across the wall of the intestine, and through the blood stream.

Low density lipoproteins (LDL)—A cholesterol carrying substance that can remain in the blood stream for a long period of time.

Neuromuscular—Involving both the muscles and the nerves that control them.

Retinitis pigmentosa—Progressive deterioration of the retina, often leading to vision loss and blindness.

Triglycerides—Certain combinations of fatty acids (types of lipids) and glycerol.

Vitamin deficiency—Abnormally low levels of a vitamin in the body.

include ataxia (poor muscle coordination), loss of deep tendon reflexes, and decreased sensation to touch, pain, and temperature.

Muscular atrophy, the weakening and loss of muscle tissue, is caused by the decreased ability of nerves to control those muscles, as well as lack of nutrients for the muscles themselves. Weakened heart muscle (cardiomyopathy) may occur. Several severe cases of weakened heart muscle resulting in early death have been reported.

Retinitis pigmentosa is progressive especially without treatment. The typical symptoms are loss of night vision and reduced field of vision. Loss of clear vision, nystagmus (involuntary movement of the eyes), and eventual paralysis of the muscles that control the eye may also occur.

QUESTIONS TO ASK YOUR DOCTOR

- What specific foods should be eliminated to control triglycerides?
- What vitamin regimen do you recommend?
- Do you have specific recommendations to help with lipid absorption?
- Are there any therapies that can help with neuromuscular symptoms?

Skeletal problems associated with ABL include various types of curvature of the spine and clubfeet. The abnormalities of the spine and feet are thought to result from muscle strength imbalances in those areas during bone growth.

Severe anemia sometimes occurs in ABL and may be partly due to deficiencies of iron and folic acid (a B vitamin) from poor absorption of nutrients. In addition, because of their abnormal shape, acanthocytes are prematurely destroyed in the blood stream.

Vitamins A, E, and K are fat soluble, meaning they dissolve in lipids in order to be used by the body. Low lipid levels in the blood means that people with ABL have chronic deficiencies of vitamins A, E, and K. Much of the neuromuscular disease seen in ABL is thought to be caused by deficiencies of these vitamins, especially vitamin E.

Approximately one-third of all individuals with ABL develop mental retardation. However, since the proportion of cases involving consanguinity is also reported to be about one-third, it is difficult to determine if mental retardation in individuals with ABL is due to the disease itself or to other effects of consanguinity. Consanguinity may also be responsible for other birth defects seen infrequently in ABL.

Diagnosis

The diagnosis of ABL begins with observations of intestinal, neuromuscular, and ocular symptoms. It is confirmed by laboratory tests showing the presence of acanthocytes and the absence of betalipoproteins and chylomicrons in the blood. Other diseases resulting in similar intestinal or neurological symptoms, and those associated with symptoms related to malnutrition and vitamin deficiency must be excluded. There is no direct test of the *MTP* gene available in the United States for routine diagnostic testing. Accurate carrier testing and prenatal diagnosis are therefore not yet available. Any couple whose child is diagnosed with ABL should be

referred for genetic counseling to obtain the most up-to-date information.

Treatment and management

The recommended treatments for ABL include diet restrictions and vitamin supplementation. Reduced triglyceride content in the diet is suggested if intestinal symptoms require it. Large supplemental doses of vitamin E (tocopherol) have been shown to lessen or even reverse the neurological, muscular, and retinal symptoms in many cases. Supplementation with a water-soluble form of vitamin A is also suggested. Vitamin K therapy should be considered if blood-clotting problems occur.

Occupational and physical therapy can assist with any muscular and skeletal problems that arise. Physicians who specialize in orthopedics, digestive disorders, and eye disease should be involved. Support groups and specialty clinics for individuals with multisystem disorders such as ABL are available in nearly all metropolitan areas.

Prognosis

Because the condition ABL is rare, there have been few individuals on which to base prognostic information. The effectiveness of vitamin supplementation and diet restrictions will vary from person to person and family to family. Lifespan may be near normal with mild to moderate disability in some, but others may have more serious and even life-threatening complications. Arriving at the correct diagnosis as early as possible is important. However, this is often difficult in rare conditions such as ABL. Future therapies, if any, will likely focus on improving lipid absorption in the digestive tract. Further study of the *MTP* gene may lead to the availability of accurate carrier testing and prenatal diagnosis for some families.

Absence of vas deferens

Definition

Absence of vas deferens is a birth defect that causes male infertility. The vas deferens are the tubes that transport sperm from the testicle to the ejaculatory tube. Absence of vas deferens is most often associated with the genetic disorder cystic fibrosis (CF). The majority of men with CF (95%) are born without either vas deferens. This condition is referred to as congenital bilateral absence of vas deferens or CBAVD. Cystic fibrosis is caused by inheriting two defective CF genes, one from each parent. Absence of vas deferens can also occur in male carriers of a single defective CF gene who do not have symptoms of CF.

Description

The vas deferens (pl. vasa deferentia), also called the spermatic duct, is a thick-walled tube about 18 inches (45 cm) long that transports sperm from the testicle to the ejaculatory duct where the sperm is combined with semen. Absence of vas deferens is usually bilateral, meaning that the tubes on each side of the body fail to form. Absence of

vas deferens does not interfere with sperm production in the testicles or with semen production. However, the semen is ejaculated without the sperm required to fertilize an egg and thus is infertile. Absence of vas deferens can also be unilateral, meaning that the vas deferens is missing from only one testicle. The male retains his fertility. Congenital absence of the vas deferens is present at birth and is distinguished from similar conditions caused by an accident or surgery. An example of surgery would be vasectomy, where the vas deferens is cut to prevent sperm from reaching the semen as a form of birth control.

Absence of vas deferens has long been recognized as a symptom of CF. While males with CF present normal levels of sex hormones, they have azoospermia (absence of sperm). CF is an often-fatal, inherited disorder that affects the cells that produce mucus, sweat, and digestive enzymes. CF leads to progressive damage to the respiratory system and chronic digestive problems. Absence of vas deferens without CF was not recognized as a separate disorder until 1992, when it was identified by a team of doctors led by Arturo Anguiano and Robert Oates. Many men with one CF-causing gene have either unilateral or bilateral absence of vas deferens without other symptoms. Still, they sometimes have mild respiratory or digestive problems. A less common cause of absence of vas deferens is a prenatal abnormality that interferes with proper differentiation in the mesonephric duct, the primitive tube that develops into the vas deferens.

Genetic profile

CF and associated CBAVD are caused by mutations (changes) in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. The *CFTR* protein forms a channel in cell membranes that enables chloride ions to move in and out of cells. Chloride ion flow helps control the water movement that is necessary for the production of thin, flowing mucus. If the *CFTR* protein is abnormal or absent, as in CF, chloride ions are prevented from exiting cells. This disrupts the normal movement of water in and out of cells and causes the production of thick, sticky mucus that blocks airways and ducts in the digestive system leading to progressive damage. CF also causes the formation of thick, sticky mucus in the male genital tract. This blocks the vasa deferentia as they are forming and causes them to deteriorate before birth.

Of the more than 1,900 known mutations that can occur in the *CFTR* gene, only 127 are known to cause CF. About 70% of CF cases in people of European ancestry are caused by a mutation called delta-F508. This is a deletion of three DNA bases in the *CFTR* gene that results in a *CFTR* protein missing a single amino acid—phenylalanine (F) at amino-acid position 508. This simple change results to all of the medical consequences of

KEY TERMS

Carrier—Having one abnormal gene for a trait, such as cystic fibrosis, and one normal gene for the trait (a heterozygote), without signs and symptoms of the disorder. A carrier can still pass the abnormal gene on to offspring.

Congenital bilateral absence of vas deferens (CBAVD)—The absence at birth of the vas deferens on each side of the male reproductive tract.

Cystic fibrosis (CF)—An inherited genetic disorder that affects many body systems, especially the lungs and digestive system, and produces absence of vas deferens in males.

Cystic fibrosis transmembrane conductance regulator (CFTR)—A protein responsible for regulating chloride movement across cells lining passageways and tubules in some tissues. Cystic fibrosis and absence of vas deferens can be caused by mutated *CFTR* genes.

Delta-F508—The most common cystic fibrosis-causing mutation in Caucasians, resulting in a defective CFTR protein due to the deletion of the amino acid phenylalanine (F) at amino-acid position 508 of the protein.

Epididymis—The mass of small ducts in which sperm mature before entering the vas deferens.

In vitro fertilization (IVF)—Fertilization of eggs removed from an ovary with male sperm using laboratory equipment, followed by implantation of the fertilized egg(s) into a woman's uterus.

Intracytoplasmic sperm injection (ICSI)—Fertilization process in which the sperm is injected directly into the cytoplasm of the egg using laboratory equipment.

Microsurgical epididymal sperm aspiration (MESA)—A surgical sperm retrieval method where a small needle is inserted into the epididymis and a syringe attached by tubing to the needle is used to withdraw the sperm under the observation of a microscope.

R117—A minor mutation in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene that can cause absence of vas deferens without causing cystic fibrosis.

Testicles—The testes and their enclosing structures.

Vas deferens (pl. vasa deferentia)—The tube that transports sperm from the testicle to the ejaculatory tube.

CF. However, this mutation is recessive, so that only children who inherit two copies of a defective *CFTR* gene—one from each parent—have CF, as well as CBAVD in males. Children who inherit a defective *CFTR* gene from one parent are “carriers” who can pass the defective gene on to their offspring. About one out of every 25 Caucasians carries a gene that can cause CF.

Stand-alone CBAVD without CF can occur in males who have inherited the delta-F508 mutation from one parent and a second mild mutation in the *CFTR* gene from the other parent. This second mutation, called R117H, changes the DNA sequence to replace the amino acid arginine (R) at position 117 of the CFTR protein with the amino acid histidine (H). This R117H mutation is dominant, so that the vas deferens may fail to develop even in males who have inherited a normal *CFTR* gene from the other parent. However, the R117H mutation does not always cause absence of vas deferens—it depends on certain other characteristics of the *CFTR* genes. A specific variant of the *CFTR* gene called 5T can also cause CBAVD. Men with CBAVD caused by *CFTR* mutations who father children through assisted reproductive technologies are at increased risk for having a child with CF or male children with CBAVD and/or CF.

Demographics

CBAVD is rare. It is responsible for only 1%–2% of all cases of male infertility. It almost exclusively affects males of European and Ashkenazi Jewish descent. It is very rare in males of African or Asian descent. When it does affect males of African or Asian descent, it is usually due to some other prenatal abnormality in the formation of the vas deferens.

Signs and symptoms

The cause of absence of vas deferens in males who do not have a mutation in the *CFTR* gene is often unknown. Some cases of absence of vas deferens are associated with other structural problems in the urinary tract.

There are no observable signs of absence of vas deferens. The first indication is usually male infertility in adulthood.

Diagnosis

The first step in determining the cause of male infertility is to ascertain if the semen contains any sperm or if the sperm are defective. If there are no sperm present,

QUESTIONS TO ASK YOUR DOCTOR

- How can you tell if my infertility is caused by absence of vas deferens?
- Should I be tested for cystic fibrosis?
- Should my partner and I have genetic testing?
- What information will genetic testing provide?
- Can I father a child by in vitro fertilization?
- How does intracytoplasmic sperm injection differ from in vitro fertilization?
- What are the chances that my child conceived through in vitro fertilization will have cystic fibrosis and/or absence of vas deferens?

the next step in diagnosis is to ascertain if sperm are produced. Determining that the testicles are of normal size and shape would suggest that they are producing sperm. With CBAVD, the testicles are normal, as are other parts of the reproductive system such as the epididymis (the tube that connects a duct at the rear of the testicle to the vas deferens). The key evidence from the physical exam is that the vasa deferentia are not palpable; they are not easy to find. Two other diagnostic indications are a low volume of semen and an acidic pH to the ejaculate.

Once a diagnosis of CBAVD has been made, the affected male should have a standard exam for CF. Tests may reveal previously unrecognized influences from *CFTR* mutations that may help in the diagnosis of future health problems. The standard diagnostic tests for CF include analysis of sweat for a high salt content and any signs of lung disease.

Genetic testing can reveal the most common mutations responsible for stand-alone CBAVD. However, it is prohibitively complicated to test for all *CFTR* mutations. Men with CBAVD who plan to use their sperm for in vitro fertilization (IVF) may undergo genetic testing to determine the risk of passing CF and/or CBAVD to their offspring.

Treatment and management

Although there is no treatment for CBAVD, the resulting infertility can be circumvented by removing sperm from the testicles for IVF. The sperm is usually retrieved by a surgical sperm retrieval method. The most effective method is microsurgical epididymal sperm aspiration (MESA). A small needle is inserted into the epididymis and a syringe attached by tubing to the needle is

used to withdraw the sperm under the observation of a microscope. Another method, called testicle sperm extraction, surgically removes a small amount of tissue from one of the testicles and extracts the sperm. This is less effective than MESA and is only used in extreme situations. The most effective method of artificial insemination for men with CBAVD is intracytoplasmic sperm injection (ICSI), in which the sperm is injected directly into the cytoplasm of the female's egg. Once the zygote (fertilized egg) starts to multiply, it is implanted in the woman's uterus.

Prognosis

Men with absence of vas deferens who do not also have CF lead normal healthy lives. They can usually father children using IVF or ICSI. Genetic testing of both parents can help prevent passing on CF and/or CBAVD to offspring. It is also possible to diagnose CF in a zygote before implantation into the uterus.

Accutane embryopathy

Definition

Accutane is the retinoid isotretinoin commonly used to treat severe acne that has not responded to other forms of treatment. Accutane embryopathy, or fetal retinoid syndrome, refers to the pattern of physical and mental birth defects that may be caused in an embryo that is exposed to synthetic vitamin A during development.

Description

Accutane is one of several synthetic drugs derived from vitamin A. The generic name for Accutane is isotretinoin. Accutane and other vitamin A derivatives are referred to as retinoids. Vitamin A is an essential nutrient for normal growth and development. It is found in foods such as green leafy and yellow vegetables, oranges, pineapple, cantaloupe, liver, egg yolks, and butter. It is also available in multivitamins and as a daily supplement. Vitamin A is important in a number of biological processes, including the growth and differentiation of the skin, bone development, and vision. Deficiency of vitamin A may lead to increased susceptibility to infection and problems with vision and growth of skin cells. The potential risks of supplemental vitamin A in a person's diet have been a matter of some debate; however, excess vitamin A during pregnancy does not seem to be associated with an increased risk for birth defects.

The same cannot be said for drugs derived from vitamin A like Accutane and other retinoids that display some of the same biologic properties as vitamin A. For this reason it is an effective method of treatment for severe cases of cystic acne, a condition characterized by painful scarring lesions. Four to five months of Accutane treatment usually leads to clearing of the acne for one year or more even after the medicine is stopped. Accutane may also be prescribed for moderate acne that has not responded to other forms of treatment. Milder cases of acne that produce scarring or other related skin disorders

may also be treated with this medication, but dermatologists prescribe Accutane only after other methods of treatment have been unsuccessful.

Common side effects of Accutane are chapped lips, dry skin with itching, mild nosebleeds, joint and muscle pain, and temporary thinning of hair. Although severe acne on its own is associated with lower self-esteem, depression including thoughts of suicide has been reported more recently as another much more serious potential side effect. No studies have been published to try to determine if Accutane use somehow makes it more likely for a person to be depressed or to attempt suicide.

The United States Food and Drug Administration (USFDA) approved the use of Accutane in September 1982 even though it had previously been shown to cause birth defects in animals. Consequently, its approval was granted with the provision that the drug label would describe its risk of causing birth defects. The patient information brochure also included information for women taking the medication about avoiding pregnancy.

The first report of an infant with Accutane-related birth defects was published in 1983. At least ten additional cases were subsequently reported to the USFDA and Centers for Disease Control and Prevention (CDC). In 1985, Dr. Edward Lammer reviewed a total of 154 pregnancies exposed to Accutane and discovered a pattern of birth defects involving the head, ears, face, and heart. Each of the pregnancies had reported the use of the drug during the first three months of pregnancy. This period is a critical and sensitive time during which the organs begin to develop. Chemical insults during this part of pregnancy often result in abnormal formation of internal organs with or without external abnormalities.

Each of the 154 pregnancies had been voluntarily reported to either the USFDA or CDC. The pregnancy outcomes included 95 elective pregnancy terminations and 59 continuing pregnancies. Of these, 12 (20%) ended in a spontaneous pregnancy loss or miscarriage, and the remaining 47 pregnancies resulted in 6 stillborn infants with obvious abnormalities, 18 live born infants with abnormalities, and 26 apparently normal infants. The abnormalities observed among the stillborn and living infants were similar, most frequently involving the head, face, heart, and central nervous system. Thus, use of Accutane during the first several months of pregnancy was shown to be associated with an increased risk of miscarriage or stillbirth, as well as with a significant risk of birth defects in living children. This pattern of abnormalities has since become known as Accutane embryopathy. The names retinoic acid embryopathy, isotretinoin embryopathy, or fetal retinoic syndrome are also occasionally used to describe the same condition, because other retinoids,

such as Tegison (etretinate), have been associated with a similar pattern of birth defects. Tegison is commonly used to treat severe psoriasis and can cause birth defects even if stopped years before becoming pregnant.

Genetic profile

Accutane embryopathy is not an inherited or hereditary type of abnormality. Rather, it is caused by exposure of a developing embryo to the drug Accutane during the first trimester of pregnancy. Accutane is a well-known, powerful teratogen, and its use any time after approximately four weeks of pregnancy is associated with a significantly increased risk for pregnancy loss or an infant with Accutane embryopathy. It is not known if the dosage of Accutane affects the occurrence of the embryopathy. If Accutane is stopped prior to conception, no increased risk for loss or birth defects is expected.

Demographics

The total number of women of reproductive age (15–44 years old) taking Accutane is unknown. However, since the 1990s, the overall number of prescriptions written for Accutane has increased over 200%. Prescriptions are evenly divided between men and women, but women 30 years old or younger account for 80% of the patients among their sex.

A Dermatologic and Ophthalmic Drug Advisory Committee was convened at the USFDA in September 2000. Patterns of Accutane use and the outcomes of Accutane-exposed pregnancies were presented at this meeting. Two overlapping sources of pregnancy data exist: one sponsored by the manufacturer of the drug, Roche Laboratories, and a second study maintained by the Slone Epidemiology Unit at the Boston University School of Public Health. Representatives from both institutions reviewed their outcome data up to that time. This data supports previous estimates of the frequency of Accutane embryopathy.

Studies were done in the 1980s through the early 2000s to measure the occurrence of embryopathy in women who used isotretinoin, usually in the context of how useful pregnancy prevention or risk management programs worked within this population. Similar to Lammer's initial findings, women taking isotretinoin had about a 25% chance of embryopathic events during pregnancy. The studies, however, focused on the pregnancy rates in women being treated with isotretinoin rather than the effects the use or dosage had on developing fetuses.

Between the years of 1999 and 2007, a population-based study in the Netherlands also evaluated compliance with pregnancy prevention protocols in women of child-bearing age taking isotretinoin and found similar

KEY TERMS

Embryo—The earliest stage of development of a human infant. The term “embryo” is usually used to refer to the first eight weeks of pregnancy. The term “fetus” is used from roughly the third month of pregnancy until delivery.

Miscarriage—Spontaneous pregnancy loss.

Psoriasis—A common, chronic, scaly skin disease.

Retinoid—A derivative of synthetic vitamin A.

Stillbirth—The birth of a baby who has died sometime during the pregnancy or delivery.

Teratogen—A factor that causes malformations in the growing embryo.

Thymus gland—An endocrine gland located in the front of the neck that houses and transports T cells, which help to fight infection.

pregnancy rates and embryopathic events. Neither the U.S. nor the Dutch studies evaluated the annual occurrence of Accutane embryopathy, but they did show that annual rates during the years the studies ran were about 1–2 per 1,000 pregnancies per year, which suggests a 26% risk of developing symptoms associated with Accutane embryopathy.

Signs and symptoms

Accutane embryopathy is characterized by a number of major and minor malformations. Each abnormality is not present in every affected individual.

Craniofacial

- Abnormalities of the ears, when present, involve both ears but may show different levels of severity ranging from mild external abnormalities to a very small or missing ear.
- Underdevelopment of the skull and facial bones that can lead to specific facial features, including a sharply sloping forehead, small jaw (micrognathia), flattened bridge of the nose, and an abnormal size and/or placing of the eye sockets and eyes.

Heart

- Structural defects, most of which require surgery to correct.

Central nervous system

- Hydrocephalus, or abnormal accumulation of fluid within the brain. This is the most common type of brain

abnormality and often is treated by placement of a shunt within the head to drain the fluid.

- Small head size (microcephaly)
- Structural or functional brain abnormalities
- Mild to moderate intellectual disability or learning disabilities later in life. Either may be present even in the absence of physical abnormalities.

Other

- Abnormal or very small thymus gland
- Cleft palate, or opening in the roof of the mouth

Diagnosis

A diagnosis of Accutane embryopathy is based on two pieces of information: (1) report of Accutane use by the mother during the first trimester of pregnancy, and (2) recognition of the physical abnormalities in an exposed infant. The latter is accomplished by a physical examination by a doctor familiar with the disorder. Special studies of the heart may be required after delivery to determine the specific nature of any structural heart defect.

Prenatal diagnosis is theoretically possible if there is knowledge of early pregnancy exposure. A prenatal ultrasound evaluation may detect abnormalities such as heart defects, hydrocephalus or microcephaly, or some craniofacial abnormalities. However, not all features of Accutane embryopathy will be apparent even with an ultrasound; thus, a careful examination after delivery is still needed for diagnosis.

Treatment and management

The care of an infant with Accutane embryopathy after delivery is primarily symptomatic. Infants with serious heart abnormalities will need to be evaluated by a heart specialist and may require surgery in order to survive. Infants with brain abnormalities such as hydrocephalus may require shunt placement soon after birth and monitoring by a brain surgeon on a regular basis. Ear malformations may be associated with hearing loss in affected children. Depending on the severity of the ear abnormality, sign language may be needed for communication. Some infants with very severe internal birth defects, particularly of the heart, may die at a young age.

Based on the features associated with Accutane embryopathy and the long-term medical care that may be required, the focus of the manufacturer of Accutane has long been on the prevention of as many pregnancies as possible. Roche Laboratories has made numerous efforts since 1982 to achieve this, including periodic changes in the drug label and attempts to increase doctor

QUESTIONS TO ASK YOUR DOCTOR

- If I take isotretinoin in the future, how long before conception should I stop taking the drug?
- What are the risks if my baby has heart surgery?
- How severe is my child's hearing loss?
- At what age can my baby's hearing be accurately checked?

and consumer awareness about the teratogenic nature of Accutane during pregnancy.

In 1988, Roche developed the Accutane Pregnancy Prevention Program (PPP), which was fully implemented in mid-1989. The goal of the PPP was to develop educational materials about Accutane for both patients and their doctors. A PPP kit included a consent form and a patient information brochure. Prescribing physicians were encouraged to obtain informed consent from all of their patients after a verbal discussion of the risks and benefits of the drug. Pregnancy tests were strongly encouraged prior to beginning treatment. The patient information brochure included information about the patient referral program sponsored by Roche. The program offered to reimburse women for the cost of a visit to their doctor to review effective methods of birth control. Finally, warnings about the risks associated with Accutane were printed directly on the box and the individual drug packages.

An Accutane tracking study was implemented to evaluate how often doctors were using the PPP kit and following other major components of the program. The results of the study revealed that many doctors were inclined to rely only on oral communication about Accutane with their patients rather than using each of the elements of the PPP kit. The patient brochure was frequently used, but other components of the kit were considered inconvenient and too time-consuming. Both Roche and the FDA agreed that certain parts of the PPP needed improvement.

Additional support came in the form of a report published in the CDC-sponsored periodical *Morbidity and Mortality Weekly Report* (MMWR) in January 2000. A group of 23 women was identified in California, all of whom had taken Accutane while pregnant. During March 1999, a representative from the CDC interviewed a total of 14 of these women in an attempt to learn why pregnancies exposed to Accutane continued to occur despite the efforts of the PPP. The factors that contributed to the occurrence of these pregnancies in the first place were

investigated. Some of the women had obtained Accutane from a source other than their doctor, such as in another country or from an associate. Another woman reported using medication left over from a previous prescription. In other cases, the prescription was filled before a pregnancy test was performed or was started before day two or three of her menstrual period.

Due to legal issues surrounding the serious side effects Accutane and its contribution to severe birth defects, Roche Pharmaceuticals discontinued its production in 2009. In 2012, lawsuits were brought against Roche by former users of Accutane who blamed the medication for their development of bowel disease.

Prognosis

Accutane embryopathy is a serious medical condition that is directly related to the maternal use of Accutane during the first trimester of pregnancy. Some individuals born with Accutane embryopathy will suffer from several different developmental disorders, but may have a normal lifespan, while others may die at a young age due to complex internal abnormalities. Mild or moderate mental disabilities are common even when there are no obvious physical features expressed.

Aceruloplasminemia

Definition

Aceruloplasminemia is an inherited disorder that causes iron in the body to slowly gather in the brain and in various internal organs of the body. The effects of the excess iron in the brain typically become apparent when a person reaches adulthood. These effects tend to get worse as the years go by. The three major manifestations include diabetes, degeneration of the retina in the eye, and neurological disease. The neurological disease includes shaking or jerking of the extremities and twitching of the eyelids, along with other muscular, coordination, and cognitive problems.

Alternate names associated with aceruloplasminemia include ceruloplasmin deficiency, familial apoceruloplasmin deficiency, ferrooxidase deficiency, and hereditary ceruloplasmin deficiency.

Description

Aceruloplasminemia results from the complete absence of iron-removing activity via ceruloplasmin, a copper-containing protein in the blood. Ceruloplasmin is important in removing iron from cells in the body. It is believed to do this by metabolizing iron, or oxidizing one form of iron (ferrous iron or Fe²⁺) into another (ferric iron, or Fe³⁺). Once it is in the ferric iron form, another protein in the blood plasma (called transferrin) can then carry it away in the bloodstream. Without ceruloplasmin, iron cannot be transported out and instead accumulates in the cells of various organs. These organs include parts of the brain, the pancreas, the liver, and the retina of the eye.

The iron builds up slowly, becoming more and more concentrated in the organs as the years pass. The iron overload not only damages organs, but may cause them

to stop working altogether. Most people who have this condition do not experience noticeable problems as children or teens. However, they begin showing symptoms once they reach adulthood, usually between the ages of 25 and 60 years of age. The symptoms typically worsen as the patient ages.

Genetic profile

Aceruloplasminemia results from a mutation in the ceruloplasmin (ferroxidase) gene (generally abbreviated CP). Aceruloplasminemia is an autosomal recessive disorder, it occurs when an individual inherits a mutated *CP* gene from each parent. Everyone has two copies of the *CP* gene. Individuals with aceruloplasminemia inherit two non-working (mutated) copies of the gene, one from each parent. Their parents are carriers when they have one mutated form of the *CP* gene and one working form of the *CP* gene. Carriers are individuals who do not develop the disorder themselves but may pass the gene for the disorder onto their children. If both parents are carriers, each of their children has a 50% chance of being a carrier, a 25% chance of inheriting the disorder, and a 25% chance of inheriting two normal *CP* gene copies. In the rare circumstance that both parents have aceruloplasminemia, all of their children will also have the disorder.

Located on chromosome 3, the *CP* gene carries the blueprint for making the protein ceruloplasmin, which actually comes in two forms. They are:

- Glycosylphosphatidylinositol-anchored (GPI-anchored) ceruloplasmin, which is made in supportive cells, called glial cells, of the nervous system. GPI-anchored ceruloplasmin metabolizes iron in the brain.
- Serum ceruloplasmin, which is made mainly in the liver. Serum ceruloplasmin metabolizes iron elsewhere in the body, but not in the brain.

Individuals who have inherited the mutated *CP* gene from both parents make ceruloplasmin that cannot function correctly. As a result, iron begins to accumulate in vital organs including the brain. These vital organs begin experiencing iron overload and eventually suffer damage.

Not all CP mutations are the same. Scientists have identified over 50 different mutations in the *CP* gene that can lead to aceruloplasminemia. More than half of all CP mutations may cause the gene to produce incomplete or otherwise ineffective ceruloplasmin proteins. In some other cases, the CP mutations may result in substitutions of amino acids, the building blocks of proteins. This leads to the production of ceruloplasmin that degrades soon after it is made and, therefore, is nonfunctional.

KEY TERMS

Anemia—A disorder resulting from insufficient red blood cells or hemoglobin in the blood.

Blood serum—The clear liquid portion of the blood.

Ceruloplasmin—A copper-containing protein that is involved in iron metabolism.

Diabetes mellitus—A group of metabolic diseases resulting from high blood-sugar concentrations.

Insulin—A hormone that is important in controlling blood-sugar levels.

Retina—The light-sensitive tissue at the back of the eyeball.

As of 2015, DNA sequencing of the *CP* gene can identify greater than 92% of the mutations that cause aceruloplasminemia. DNA sequencing is the molecular determination of the precise sequence of nucleotides in a specific gene or genes. DNA sequencing of the *CP* gene is done by reading the coding portion (exons), and the junctions between the non-coding and coding regions of the *CP* gene. By reading the genetic code at these important functional regions of the *CP* gene, over 92% of the mutations in this gene will be detected. It is important to remember that not all mutations can be detected by DNA sequencing. Other forms of DNA testing may be necessary.

Once the disease causing mutations are found in the affected individuals, it is possible to use DNA testing for carrier testing of other relatives, prenatal diagnosis for at-risk pregnancies, and predictive testing for asymptomatic adult relatives at risk to develop aceruloplasminemia.

Demographics

Aceruloplasminemia is a rare genetic disorder that affects individuals worldwide. According to the National Institutes of Health, its overall prevalence is unknown, although studies in Japan indicate that it affects approximately 1 in 2,000,000 individuals there. Aceruloplasminemia affects males and females equally.

Signs and symptoms

Individuals with aceruloplasminemia usually do not experience any problems as children or teens. The first symptoms may appear as early as age 25, but sometimes do not manifest until the individual is middle-aged or older. Symptoms vary from one individual to the next and often include neurological problems.

Symptoms may include one or more (typically several) of the following:

- tremors
- involuntary jerks of the body
- twitching of the eyelids (also known as blepharospasm)
- involuntary facial movements, especially grimacing
- difficulty speaking
- difficulty walking
- Stiffness
- coordination problems

Besides these more common symptoms, some individuals may experience attacks on their cognitive function. Some may develop depression or other psychiatric problems. Furthermore, they may face dementia once they reach middle age or older.

In addition to these symptoms, many individuals with aceruloplasminemia also develop the following conditions, often before other aceruloplasminemia symptoms appear:

- Anemia, resulting ultimately from a deficiency of iron in the blood
- Diabetes mellitus, resulting from damage to insulin-making cells in the pancreas. Insulin is important in controlling blood-sugar levels.

Both anemia and diabetes mellitus are associated with their own sets of symptoms.

Sometimes, a visit to the eye doctor for a routine exam can reveal a sign of aceruloplasminemia—a sign that is not evident to the patient. The disorder often causes damage to the retina, which is the light-sensitive tissue at the back of the eyeball. This is evident as small yellowish-white spots as well as damaged tissue that the doctor can readily see during an eye examination. The damage usually causes no vision problems and has no other noticeable effects on the patient.

Diagnosis

Examination

A doctor may suspect aceruloplasminemia if a patient reports one or more of the symptoms listed above, particularly when combined with already-diagnosed anemia or diabetes mellitus, or with retina damage as discovered in an eye examination. To make a diagnosis of aceruloplasminemia, however, the doctor will also order blood or other tests. DNA sequencing of the *CP* gene may be done to confirm the diagnosis.

Tests

A doctor will typically order blood tests, perhaps combined with magnetic resonance imaging (MRI) to rule out or confirm aceruloplasminemia. Blood tests serve several purposes, including whether any of the following apply:

- a lack of serum ceruloplasmin.
- too little iron (less than 45 5g/dL compared to a normal range of 60-180 5g/dL in males, and 60-140 5g/dL in females) and/or too little copper (less than 10 5g/dL compared to a normal range of 70-125 5g/dL) in the blood, which are signs of dysfunctional ceruloplasmin or its complete absence.
- a high concentration of the primary iron-storage protein, called ferritin (850-4000 ng/mL compared to a normal range of 45-200 ng/mL in males and 30-100 ng/mL in females).
- higher-than-normal concentration of hepatic iron (the normal level of iron in the liver is less than 36 μ mol/g).

The doctor may use MRI results to determine whether the patient's liver and parts of the brain show the presence of accumulated iron.

Treatment and management

No cure exists for aceruloplasminemia, but doctors can offer various treatment options. These may include the following:

- Iron chelating agents, which attract and bind with excess iron so that it can be removed from the body by way of the bloodstream and ultimately the urine and feces. Iron chelating agents are used to lower the concentration of iron in the brain and liver, to lessen the concentration of ferritin in blood serum, and to slow or stop the progression of neurologic symptoms. A commonly used iron chelating agent is desferrioxamine (also known as deferoxamine or desferol). Treatment with desferrioxamine typically involves nightly infusions by a pump over a course of days or weeks.
- Combination of plasma (given as fresh-frozen plasma or FFP) and an iron chelating agent.
- Repeated doses of plasma to ease neurologic symptoms.

The doctor may also recommend that the patient take zinc supplements and vitamin E or other antioxidants to help prevent damage to various organ tissues.

Prognosis

Most individuals who have aceruloplasminemia experience no symptoms until they are at least 25 years old and possibly not for three or four more decades after that. The various treatment options may slow the disease's progression or lessen, and possibly halt, some of

QUESTIONS TO ASK YOUR DOCTOR

- I have heard that other iron chelating agents are available besides desferrioxamine. Are the treatment regimens for these less demanding and will they work as well?
- My spouse and I are both carriers and would like to have a child. Is prenatal testing available to determine whether a baby has aceruloplasminemia?
- Is there a way, perhaps through preimplantation genetic diagnosis, to ensure that we have a baby that does not have the disorder?
- I have a relative with aceruloplasminemia. Should I be tested for this disorder? Should my children be tested?
- My child has just been diagnosed with aceruloplasminemia. Are there certain foods I should avoid serving?

the symptoms associated with it. The symptoms generally worsen with age. Many patients with this disorder also develop diabetes mellitus and anemia.

Prevention

There is no way to prevent aceruloplasminemia. It is an inherited disorder. Adults who are carriers may wish to undergo genetic counseling before deciding to have children so that they understand the risks. If parents who are carriers do have a child, they should inform their doctor and ask to have their child tested early for the disorder. If parents are not aware that they are carriers and have a child born with aceruloplasminemia, they should ask to have themselves and their other children tested. If necessary, parents should ask about possible preventative treatments, such as administration of desferrioxamine. Brothers and sisters of a child with the disorder have a 25% chance of having the disorder themselves, and a 50% chance of being a carrier for the disorder.

All individuals diagnosed with this condition should have yearly glucose testing for diabetes mellitus. This will allow the patient to begin diabetes treatment as early as possible. In children with aceruloplasminemia, this testing should start in the teen years.

Persons with aceruloplasminemia should avoid taking iron supplements even if they are anemic. Studies show that the added iron causes aceruloplasminemia to progress more quickly.

Caregivers of older patients should remain observant for signs of depression or dementia and report their concerns to the patient's doctor.

Achondrogenesis

Definition

Achondrogenesis is a group of disorders of cartilage and bone formation in which skeletal growth is severely affected. The condition is usually fatal prenatally or early in life.

Description

Achondrogenesis is a name given to a group of disorders that represent the most severe form of congenital chondrodysplasia, or malformations of bones and cartilage that are present at birth. Achondrogenesis is considered a lethal form of infantile dwarfism. Dwarfism is a condition that leads to extremely short stature. In achondrogenesis, the abnormalities in cartilage formation lead to abnormalities in bone formation. The lethality of the disorder is thought to result from difficulty breathing, probably due to the infant's having a very small chest. Achondrogenesis usually results in a stillborn infant or death shortly after delivery.

Achondrogenesis is subdivided into two major types, type 1 and type 2. Type 1 can further be subdivided into type 1A and type 1B. Types 1A and 1B are distinguished by microscopic differences in the cartilage and cartilage-forming cells. Cartilage-forming cells (chondrocytes) are abnormal in type 1A, whereas the cartilage matrix itself is abnormal in type 1B. The current classification, introduced by Jürgen Spranger and colleagues in 1974, is based on genetic findings. The three classifications have different genetic causes.

Synonyms

Synonyms for achondrogenesis include chondrogenesis imperfecta; hypochondrogenesis; lethal neonatal dwarfism; lethal osteochondrodysplasia; and neonatal dwarfism. Achondrogenesis type 1A is also known as Houston-Harris-type achondrogenesis; achondrogenesis type 1B is also known as Fraccaro-type achondrogenesis; and achondrogenesis type 2 is also known as Langer-Saldino-type achondrogenesis.

Genetic profile

Achondrogenesis type 1A is the least common and least well understood form of the disorder. The gene responsible for type 1A was identified in 2010 as the *TRIP11* gene on chromosome 14 at 14q32.12. This gene encodes a protein known as the Golgi microtubule-associated protein 210 (GMAP-210). GMAP-210 is essential in moving proteins from the endoplasmic reticulum of a cell to the Golgi apparatus. Without GMAP-210, the proteins remain in the endoplasmic reticulum, which swells up. Loss of function in the Golgi apparatus is particularly damaging in cells responsible for bone and cartilage formation, which explains the connection between mutations in the *TRIP11* gene and achondrogenesis. Type 1A does follow an autosomal recessive pattern of inheritance.

Achondrogenesis type 1B also follows an autosomal recessive pattern of inheritance. It results from mutations

KEY TERMS

Chondrocyte—A specialized type of cell that secretes the material which surrounds the cells in cartilage.

Endoplasmic reticulum—A network of tubules and flattened sacs that serve a variety of functions within a cell, ranging from protein transport to the synthesis of carbohydrate and fat molecules.

Fetal hydrops—A condition in which there is too much fluid in the fetal tissues, fetal cavities, or both.

Golgi apparatus—An organelle within cells that packages proteins for secretion outside the cell. Also called the Golgi body, it is named for the Italian physician Camillo Golgi, who first identified it in 1897.

Micromelia—The state of having extremely short limbs.

Ossification—The process of the formation of bone from its precursor, a cartilage matrix.

Polyhydramnios—A condition in which there is too much fluid around the fetus in the amniotic sac, seen in about 1% of pregnancies.

in the diastrophic dysplasia sulfate transporter gene (*SLC26A2*), which is located on the long arm of chromosome 5 (5q32 specifically). Abnormalities in the *SLC26A2* gene (also known as the *DTDST* gene) result in the inability of cartilage cells to take up needed sulfate ions. Without these ions, cartilage structure and bone formation are severely disrupted.

The severity of mutation determines which disorder the patient will have. The most severe of these disorders is type 1B. Since both types 1A and 1B follow autosomal recessive patterns of inheritance, the chance of parents having another child with the disorder after having the first child is 25% for both disorders.

Similar to achondrogenesis type 1B, achondrogenesis type 2 represents the most severe form of a group of disorders resulting from the mutation of a single gene—the collagen type 2 gene (*COL2A1*), located on the long arm of chromosome 12 (12q13.11 specifically). In addition to its role in development and growth, collagen type 2 plays an important structural role in cartilage formation and in the ability of cartilage to resist compressive forces. Type 2 achondrogenesis, however, does not follow an autosomal recessive pattern of inheritance. Most of the mutations that cause type 2 are new mutations, meaning they are not passed from parents to children. Also, most of these

mutations are considered autosomal dominant. However, some family members of affected children may have the mutant gene without having the disease. This pattern is not a classical dominant pattern and implies the involvement of other genes in the disease process.

Demographics

Achondrogenesis is equally rare in males and females of all races in the United States and worldwide. Although the exact incidence is unknown, one estimate places the incidence at 1 case in every 40,000 to 60,000 live births.

Signs and symptoms

Traits found in all subtypes of achondrogenesis

All infants with achondrogenesis share these characteristics: an extremely short neck, underdeveloped lungs, a protuberant abdomen, low birth weight, extremely short limbs (micromelia) and other skeletal abnormalities. The most common defining feature of this condition is the extreme shortness of the limbs.

Fetuses with achondrogenesis may also have a condition known as polyhydramnios. The symptoms of polyhydramnios include too much fluid around the fetus in the amniotic sac, too much fluid in the fetal tissues, and too much fluid in the fetal cavities. Having too much fluid in the fetal tissues or fetal cavities constitutes a condition known as fetal hydrops (hydrops fetalis). Infants with achondrogenesis are also often born in the breech position (hindquarters first).

Differences in traits shared by all subtypes of achondrogenesis

Although all the subtypes of achondrogenesis share some characteristics, there are differences in some of these characteristics between subtypes. Type 1 achondrogenesis is generally considered to be more severe than type 2. This consideration is supported by the shorter limbs found in type 1 and the lower average birth weight of type 1 infants compared to type 2 infants. Although any birth weight below 5.5 lbs (2,500 g) is considered to be low, type 1 infants average 2.6 lbs (1,200 g), whereas type 2 infants average 4.6 lbs (2,100 g). In addition, both groups have a number of subtle skeletal abnormalities in addition to those already discussed.

Traits found in type 1 achondrogenesis not shared by type 2

Type 1 achondrogenesis has two non-subtle characteristics that type 2 does not. Type 1 is often accompanied by abnormal connections either on the inside of the infant's heart or in the major blood vessels leading to and away from

QUESTIONS TO ASK YOUR DOCTOR

- Can you recommend a support group?
- Are there any supportive or comfort measures I can offer my baby?
- What is the likelihood of having additional children with this disorder?
- What type of testing is recommended before conceiving future children?

the heart. These defects are formally known as either atrial septal defects, ventral septal defects, or a patent ductus arteriosus. These connections allow oxygenated blood and deoxygenated blood to mix. Normally, oxygenated and deoxygenated blood flows are separated in the circulatory system to ensure enough oxygen makes it to important tissues like the brain. Mixing the blood results in less oxygen being pumped into the body and insufficient oxygenation of tissues around the body.

The other type 1 characteristic is incomplete ossification. Ossification is the process of bone formation. In type 1A, incomplete ossification can be seen in many bones, including the skull. In type 1B, the skull is ossified, but bones other than the skull reveal incomplete ossification. No deficiency in ossification can be seen in type 2 achondrogenesis.

Diagnosis

Prenatal diagnosis of a skeletal disorder may be made by ultrasound. DNA testing may be used to determine the type of disorder or to confirm the presence of a suspected disorder. Genetic tests available for all three types of achondrogenesis include deletion/duplication analysis, target variant analysis, and sequence analysis of the entire coding region of the gene in question. Otherwise, diagnosis may be made by the physical appearance of the infant at birth, x-rays, or both. DNA analysis or a microscopic examination of cartilage tissues may be used to identify the type of disorder.

Treatment and management

There is no treatment for the underlying disorder. Parents should consider mental health and genetic counseling to deal with the grief of losing a child and to understand the risks of the disorder recurring in subsequent children. Support groups may be helpful in the pursuit of these goals. It is important for genetic counseling purposes to determine the type of achondrogenesis that

affected the child, since different types of achondrogenesis carry very different prognoses for future children.

Prognosis

This disorder is fatal at birth or soon after. Type 1 is considered more severe, partly because infants with type 1 are more likely to be stillborn and generally succumb to the disorder earlier than infants with type 2 achondrogenesis.

Achondroplasia

Definition

Achondroplasia is a common form of dwarfism or short stature due to an autosomal dominant mutation (a mutation on one of the first 22 “non-sex” chromosomes) that causes an individual to have short stature with disproportionately short arms and legs, a large head, and distinctive facial features, including a prominent forehead and a flattened midface.

Description

Achondroplasia is a genetic form of dwarfism due to a problem of bone growth and development. There are many causes for dwarfism, including hormone imbalances and metabolic problems. Achondroplasia belongs to a class of dwarfism referred to as a chondrodysplasia or skeletal dysplasia. All skeletal dysplasias are the result of a problem with bone formation or growth. There are over 100 different types of skeletal dysplasia. Achondroplasia is the most common and accounts for half of all known skeletal dysplasias.

Achondroplasia is easily recognizable. Affected individuals have disproportionately short stature, large heads with characteristic facial features, and disproportionate shortening of their limbs. Most individuals with achondroplasia have a normal IQ. The motor development of infants is delayed due to hypotonia (low muscle tone) and their physical differences (large heads and small bones). The motor development of children with achondroplasia eventually catches up with that of their peers. Individuals with achondroplasia can have medical complications that range from mild to severe. Because of the differences in their bone structure, these individuals are prone to middle ear infections. They are also at risk for neurological problems due to spinal cord compression. The spinal canal (which holds the spinal cord) is smaller

A man with the characteristic physical features of achondroplasia. (Scott Camazine/Alamy)

than normal in people with achondroplasia. The American Academy of Pediatrics' Committee on Genetics has developed guidelines for the medical management of children with achondroplasia.

The short stature of achondroplasia can be socially isolating and physically challenging. Most public places are not adapted to individuals of short stature, which can limit activities. Children and adults with achondroplasia can be socially ostracized due to their physical appearance. Many people erroneously assume that individuals with achondroplasia have limited abilities. It is very important to increase awareness with educational programs and to take proactive steps to foster self-esteem in children with achondroplasia.

Genetic profile

Achondroplasia is caused by a mutation, or change, in the fibroblast growth factor receptor 3 gene (*FGFR3*) located on the short arm of chromosome 4.

Genes contain the instructions that tell a body how to form. They are composed of four different chemical bases—adenine (A), thymine (T), cytosine (C), and guanine (G). These bases are arranged like words in a sentence, and the specific order of these four bases provides the instructions that a cell needs in order to form a protein.

FGFR (fibroblast growth factor receptor) genes provide the instruction for the formation of a cell receptor. Every cell in the body has an outer layer, called a cell membrane, that serves as a filter. Substances are transported into and out of the cells by receptors located on the surface of the cell membrane. Every cell has hundreds of different types of receptors. The fibroblast growth factor receptor transports fibroblast growth factors into a cell. Fibroblast growth factors play a role in the normal growth and development of bones. When the receptors for fibroblast growth factors do not work properly, the cell does not receive enough fibroblast growth factors, which results in abnormal growth and development of bones.

Achondroplasia is caused by mutations in the *FGFR3* gene. Two specific mutations account for approximately 99% of achondroplasia. The *FGFR* gene is composed of 2,520 bases. In a normal (non-mutated) gene, base number 1138 is guanine (G). In most individuals with achondroplasia (98%), this guanine (G) has been replaced with adenine (A). In a small number of individuals with achondroplasia (1%), this guanine (G) has been replaced with cytosine (C). Both of these small substitutions cause a change in the fibroblast growth factor receptor (FGFR) that affects the function of this receptor.

Mutations in the *FGFR3* gene are inherited in an autosomal dominant manner. Every individual has two *FGFR3* genes—one from their father and one from their mother. In an autosomal dominant disorder, only one gene has to have a mutation for the person to have the disorder. Over 80% of individuals with achondroplasia are born to parents with average stature. Their achondroplasia is the result of a *de novo* or new mutation that arises spontaneously. No one knows the cause of *de novo* mutations or why they occur so frequently in achondroplasia. For reasons that are not yet understood, most new mutations occur in the *FGFR3* gene that is inherited from the average-size father.

An individual with achondroplasia has a 50% chance of passing on their changed (mutated) gene to their children. An achondroplastic couple (both parents have achondroplasia) has a 25% chance that they will have a child with average stature, a 50% chance that they will have a child with one achondroplasia gene (a heterozygote), and a 25% chance that a child will get two copies of the achondroplasia gene (a homozygote). Babies with homozygous achondroplasia are much more severely

affected than those with a single achondroplasia gene. These infants generally die very shortly after birth because of breathing problems caused by an extremely small chest.

Demographics

Because individuals with other forms of dwarfism are often misdiagnosed with achondroplasia, the exact incidence of achondroplasia is unknown. Estimates of the incidence of achondroplasia vary between one in 15,000 to one in 40,000 births. One European study found a prevalence of 3.72 per 100,000 births. It is estimated that there are approximately 15,000 individuals with achondroplasia in the United States and 65,000 worldwide. Achondroplasia affects males and females in equal numbers and occurs in all races and ethnic groups.

Signs and symptoms

Individuals with achondroplasia have disproportionately short stature, large heads with characteristic facial features, and rhizomelic shortening of their limbs.

(Rhizomelic means “root limb.”) Rhizomelic shortening of the limbs means that those segments of a limb closest to the body (the root of the limb) are more severely affected. In individuals with achondroplasia, the upper arms are shorter than the forearms, and the upper leg (thigh) is shorter than the lower leg.

In addition to shortened limbs, individuals with achondroplasia have other characteristic limb differences. They also have a limited ability to rotate and extend their elbows. They generally develop bowed legs and may have in-turned toes. Their hands and feet are short and broad, as are their fingers and toes. Their hands have been described as having a “trident” configuration. This term is based upon the trident fork used in Greek mythology and describes the unusual separation of their middle fingers. This unusual separation gives their hands a “three-pronged” appearance with the thumb and two small fingers on the side and the index and middle finger in the middle.

Individuals with achondroplasia have similar facial features and a large head (megalencephaly) due to the difference in the growth of the bones of the face and head.

Achondroplasia: pedigree analysis chart (Gale)

The exact reason for the increase in head size is not known, but it reflects increased brain size and can sometimes be due to hydrocephalus. People with achondroplasia have a protruding forehead (frontal bossing) and a relatively prominent chin, in part due to the relative flatness of their midface. While people with achondroplasia do resemble one another, they also resemble their family of origin.

Individuals with achondroplasia have shortening of their long bones. Women with achondroplasia have an average adult height of 48 in. (122 cm). Men have an average adult height of 52 in. (132 cm).

Diagnosis

Achondroplasia is generally diagnosed by physical examination at birth. The characteristic findings of short stature, rhizomelic shortening of the limbs, and specific facial features become more pronounced over time. In addition to being diagnosed by physical examination, individuals with achondroplasia have some specific bone changes that can be seen on an x ray including a smaller spinal canal and a small foramen magnum. The foramen magnum is the opening at the base of the skull. The spinal cord runs from the spinal canal through the foramen magnum and connects with the brain.

The diagnosis of achondroplasia can also be made prenatally either by ultrasound (sonogram) or by prenatal DNA testing. Sonograms use sound waves to provide an image of a fetus. The physical findings of achondroplasia (shortened long bones, trident hand) can be detected in the third trimester (last three months) of a pregnancy. Prior to the last three months of pregnancy, it is difficult to use a sonogram to diagnose achondroplasia, because the physical features may not be obvious. Because of the large number of skeletal dysplasias, it can be very difficult to diagnose achondroplasia definitively by sonogram. Many other dwarfing syndromes can look very similar to achondroplasia on a sonogram.

Prenatal testing can also be done using DNA technology. A sample of tissue from a fetus is obtained by either chorionic villus sampling (CVS) or amniocentesis. Chorionic villus sampling is generally done between 10 and 12 weeks of pregnancy, and amniocentesis is done between 16 and 18 weeks of pregnancy. Chorionic villus sampling involves removing a small amount of tissue from the developing placenta. The tissue in the placenta contains the same DNA as the fetus. Amniocentesis involves removing a small amount of fluid from around the fetus. This fluid contains some fetal skin cells. DNA can be isolated from these skin cells. The fetal DNA is then tested to determine whether it contains either of the two mutations responsible for achondroplasia.

X ray of achondroplasia, a common cause of dwarfism. It occurs as a sporadic mutation in approximately 80% of cases (often associated with advanced paternal age) or it may be inherited as an autosomal dominant genetic disorder. (Clinical Photography, Central Manchester University Hospitals NHS Foundation Trust, UK/Science Source)

Prenatal DNA testing for achondroplasia is not routinely performed in low-risk pregnancies. This type of testing is generally limited to high-risk pregnancies, such as those in which both parents have achondroplasia. It is particularly helpful in determining whether a fetus has received two abnormal genes (homozygous achondroplasia). This occurs when both parents have achondroplasia, and each of them passes on their affected gene. The baby gets two copies of the achondroplasia gene. Babies with homozygous achondroplasia are much more severely affected than those with heterozygous achondroplasia. Infants with homozygous achondroplasia generally die shortly after birth due to breathing problems caused by an extremely small chest. The prenatal detection rate is about 70%.

DNA testing can also be performed on blood samples from children or adults. This is usually done if there

is some doubt about the diagnosis of achondroplasia or in atypical cases.

Treatment and management

There is no cure for achondroplasia. The recommendations for the medical management of individuals with achondroplasia have been outlined by the American Academy of Pediatrics' Committee on Genetics. The potential medical complications of achondroplasia range from mild (ear infections) to severe (spinal cord compression). By being aware of the potential medical complications and catching problems early, it may be possible to avert some of their long-term consequences. An individual with achondroplasia may have some, all, or none of these complications.

All children with achondroplasia should have their height, weight, and head circumference measured and plotted on growth curves specifically developed for children with achondroplasia. Measurements of head circumference are important to monitor for the development of hydrocephalus—a known but rare (5%) complication of achondroplasia. Hydrocephalus (or water on the brain) is caused by an enlargement of the fluid-filled cavities of the brain (ventricles) due to a blockage that impedes the movement of the cerebrospinal fluid. Suspected hydrocephalus can be confirmed using imaging techniques such as a CT or MRI scan and can be treated with neurosurgery or shunting (draining) if it causes severe symptoms. Any child displaying neurologic problems such as lethargy, abnormal reflexes, or loss of muscle control should be seen by a neurologist to make sure they are not experiencing compression of their spinal cord. Compression of the spinal cord is common in individuals with achondroplasia because of the abnormal shape and small size of their foramen magnum (opening at the top of the spinal cord).

All children with achondroplasia should be monitored for sleep apnea, which occurs when an individual temporarily stops breathing during sleep. This can occur for several reasons, including obstruction of the throat by the tonsils and adenoids, spinal cord compression, and obesity. Individuals with achondroplasia are more prone to sleep apnea due to the changes in their spinal canal and foramen magnum, and because of their short necks. Treatment for sleep apnea depends on its cause. Obstructive sleep apnea is treated by surgically removing the tonsils and adenoids. Neurosurgery may be necessary to treat sleep apnea due to spinal cord compression. Weight management may also play a role in the treatment of sleep apnea.

Other potential problems in children with achondroplasia include overcrowding of the teeth (dental

KEY TERMS

Fibroblast growth factor receptor gene—A type of gene that codes for a cell membrane receptor involved in normal bone growth and development.

Rhizomelic—Describes disproportionate shortening of the upper part of a limb, compared to the lower part of the limb.

malocclusion), speech problems (problems with articulation), and frequent ear infections (otitis media). Dental malocclusion (overcrowding of teeth) is treated with orthodontics. All children with achondroplasia should be evaluated by a speech therapist by two years of age because of possible problems with the development of clear speech (articulation). Articulation problems may be caused by orthodontic problems. Due to the abnormal shape of the eustachian tube, individuals with achondroplasia are very prone to ear infections. Approximately 80% of infants with achondroplasia have an ear infection in the first year of life. About 78% of these infants require ventilation tubes in the ears to decrease the frequency of ear infections.

Weight management is extremely important for an individual with achondroplasia. Excess weight can exacerbate many of the potential orthopedic problems in an individual with achondroplasia, such as bowed legs, curvature of the spine, and joint and lower back pain. Excess weight can also contribute to sleep apnea. Development of good eating habits and appropriate exercise programs should be encouraged in individuals with achondroplasia. These individuals should discuss their exercise programs with their health care providers. Because of the potential for spinal cord compression, care should be used in choosing appropriate forms of exercise.

The social adaptation of children with achondroplasia and their families should be closely monitored. Children with visible physical differences can have difficulties in school and socially. Support groups such as Little People of America can be a source of guidance on how to face these issues. It is important that children with achondroplasia not be limited in activities that pose no danger. In addition to monitoring their social adaptation, every effort should be made to physically adapt their surroundings for convenience and to improve independence. Physical adaptations can include stools to increase accessibility, and lowering of switches and counters.

Two treatments have been used to try to increase the final adult height of individuals with achondroplasia—limb-lengthening and growth hormone therapy. There

QUESTIONS TO ASK YOUR DOCTOR

- What course of medical management is recommended?
- What specific form of exercise do you recommend?
- What are the benefits and risks of growth hormone therapy?
- What are the risks and benefits of limb lengthening?

are risks and benefits to both treatments, and they are still considered experimental.

Limb-lengthening involves surgically attaching external rods to the long bones in the arms and legs. These rods run parallel to the bone on the outside of the body. Over a period of 18 to 24 months, the tension on these rods is increased, which results in the lengthening of the underlying bone. This procedure is long and costly and has potential complications such as pain, infections, and nerve problems. Limb-lengthening can increase overall height by 12 to 14 inches (30.5–35.6 cm). It does not change the other physical manifestations of achondroplasia, such as the appearance of the hands and face. This is an elective surgery, and individuals must decide for themselves whether it would be beneficial to them. The optimal age to perform this surgery is not known.

Growth hormone therapy has been used to treat some children with achondroplasia. Originally, there was doubt about the effectiveness of this treatment, because children with achondroplasia are not growth hormone deficient. However, studies have shown that rate of growth in children with achondroplasia treated with growth hormone does increase during the first two years of treatment. For maximal effect, it is recommended that growth hormone therapy be started between ages one and six years. No studies suggest that long-term growth hormone therapy beyond two years spurs additional height gain.

Prognosis

The prognosis for most people with achondroplasia is very good. In general, they have minimal to moderate medical problems and normal IQ, and most achieve success and have a long life regardless of their stature. The most serious medical barriers to an excellent prognosis are the neurological complications that can arise in achondroplasia. Spinal cord compression is thought to increase the risk for sudden infant death syndrome (SIDS) to 7.5% in infants with achondroplasia and can

lead to life-long complications such as paralysis if untreated. Obesity can increase the risk for heart disease, and some studies have revealed an increased risk of unexplained death in the fourth and fifth decade of life.

Successful social adaptation plays an important role in the ultimate success and happiness of an individual with achondroplasia. It is very important that the career and life choices of an individual with achondroplasia not be limited by preconceived ideas about their abilities.

ACHOO syndrome

Definition

ACHOO syndrome is a generally benign condition characterized by sudden, uncontrollable sneezing after viewing a bright light.

Description

The ACHOO syndrome, standing for autosomal dominant compelling helio-ophthalmic outburst syndrome, is an inherited condition where a person will involuntarily sneeze after seeing a bright light. A person with this condition will sneeze multiple times, and in rare cases may sneeze 30–40 times. The syndrome is usually more intense if the person with the condition moves suddenly from darkness into an area with bright lights or sunlight.

Genetic profile

The ACHOO syndrome is thought to be inherited in an autosomal dominant pattern. This means that only one copy of the abnormal gene needs to be present for the syndrome to occur. If one parent has the condition, their children will have a 50% chance of also having the syndrome. One physician reported the condition in a family where it was observed in the father and his brother but not seen in the father's mother or his wife. Both the father and brother would sneeze twice when going from an area of darkness to an area of light. At four weeks of age, the father's daughter also started to sneeze whenever she was moved into bright sunlight.

Because of the relatively benign nature of the condition, there has been no reported scientific work trying to locate the gene responsible for the syndrome.

Demographics

Occurrence of the ACHOO syndrome is widespread in the general population. The few well-documented studies performed report the condition as being present in 23%–33% of individuals. Men seem to be affected more

KEY TERMS

Allergy—Condition in which immune system is hypersensitive to contact with allergens; an abnormal response by the immune system to contact with an allergen; condition in which contact with allergen produces symptoms such as inflammation of tissues and production of excess mucus in respiratory system.

Antibody—A protein produced by the mature B cells of the immune system that attach to invading microorganisms and target them for destruction by other immune system cells.

Antigen—A substance or organism that is foreign to the body and stimulates a response from the immune system.

Hypersensitivity—A process or reaction that occurs at above normal levels; overreaction to a stimulus.

Immune response—Defense mechanism of the body provided by its immune system in response to the presence of an antigen, such as the production of antibodies.

Immune system—A major system of the body that produces specialized cells and substances that interact with and destroy foreign antigens that invade the body.

than women. Studies on the occurrence of the syndrome in various ethnic groups are very limited. One study showed differences between whites and non-whites, while another study showed no difference.

ACHOO syndrome: pedigree analysis chart (Gale)

QUESTIONS TO ASK YOUR DOCTOR

- What allergy medications do you recommend?
- Should I take allergy medications on a regular basis?
- What is the risk of long-term allergy medication?
- Do you have a recommendation for decreasing the number of sequential sneezes?

Signs and symptoms

The prominent symptom of people with the ACHOO syndrome is sudden, involuntary sneezing when they see a bright light or sunlight. The way in which sneezing is triggered is not very well understood, but there are several theories that attempt to explain the syndrome.

One theory is that people who have the ACHOO syndrome have a hypersensitive reaction to light, just as some people have a sensitivity to cat hairs or pollen. When a person with the syndrome is exposed to a bright light, the same mechanism in the body that triggers a sneeze due to an irritant such as pollen somehow confuses light with that irritant and causes a sneeze to occur. Another idea is that the sneeze reflex in people with the ACHOO syndrome is somehow linked to real nasal allergies, although this does not explain the syndrome in people without nasal allergies. A third theory is that people with the ACHOO syndrome are very sensitive to seeing bright light. The sneeze reflex of the syndrome can then be thought of as an involuntary defense reaction against bright light; when the person sneezes, they automatically close their eyes.

Diagnosis

The ACHOO syndrome is diagnosed simply by observing the sneezing pattern of a person and by looking into the sneezing patterns of the person's close relatives. If the person seems to sneeze every time they are exposed to a bright light, and if their parents and offspring do the same, then the diagnosis of the ACHOO syndrome can be made.

Currently, there are no known blood tests or other medical tests that can help diagnose the syndrome.

Treatment and management

There are no specific treatments for the ACHOO syndrome. Common measures, such as wearing sunglasses, can help people who are severely affected.

There have been reports that people who have nasal allergies have a higher incidence of the ACHOO syndrome. Therefore, it is sometimes assumed that medications that are used for allergies, such as antihistamines, could perhaps play a beneficial role in the ACHOO syndrome. However, no studies have successfully demonstrated that the syndrome is relieved by this type of medication. Alternative medicine, including homeopathy and herbal medicine, recommends a wide range of remedies for nasal allergies; these may accordingly also be helpful for the ACHOO syndrome.

Prognosis

People with the ACHOO syndrome generally have the condition for life. There is no evidence showing that the ACHOO syndrome in any way affects a person's lifespan.

Acrocallosal syndrome (ACLS), Schinzel type; Joubert syndrome; and related disorders

Definition

Acrocallosal syndrome, Schinzel type is a rare congenital disorder in which the individual has absence or only partial formation of the corpus callosum. This is accompanied by skull and facial malformations with some degree of finger or toe malformations. Individuals

Acrocallosal syndrome: pedigree analysis chart (Gale)

may display motor delay and intellectual disability. The cause of this genetic disorder is unknown, and the severity of the symptoms varies by individual.

Description

Acrocallosal syndrome, Schinzel type also called Schinzel Acrocallosal Syndrome, was first described by Schinzel in 1979. Related syndromes include: Joubert Syndrome, Joubert Syndrome 12, Hallux duplication, postaxial polydactyly, and absence of corpus callosum. The term “acrocallosal” refers to the involvement of the acra (fingers and toes) and the corpus callosum, the thick band of fibers joining the hemispheres of the brain. Reported in both males and females, the cause of the disorder is unknown. The major characteristic of the syndrome is the incomplete formation (hypoplasia) or absence (agenesis) of the corpus callosum. Facial appearance is typically similar among affected people. This includes a prominent forehead, an abnormal increase in the distance between the eyes (hypertelorism), and a large head (macrocephaly). Individuals have a degree of webbing or fusion (syndactyly), or duplication (polydactyly) of the fingers and toes. Occasionally, those affected may have a short upper lip, cleft palate, cysts that occur within the cranium (intracranial), hernias, or may develop seizure disorders. Less frequently, affected children have congenital heart defects, internal organ (visceral) or kidney (renal) abnormalities.

Moderate to severe intellectual disability is reported with acrocallosal syndrome. Individuals usually display some form of poor muscle tone (hypotonia) with an expected delay or absence of motor activities, walking, and talking. There is great variation of functioning with this disorder, ranging from normal development to severe mental and motor disability.

Genetic profile

Acrocallosal syndrome, Schinzel type; Joubert syndrome; and related disorders are a group of autosomal recessive syndromes. This means that both parents must contribute the altered form of the gene for the affected child to inherit the disorder. This syndrome and the related disorder, hydroletharus syndrome, have recently been reported to be caused by mutations in the *KIF7* gene and over 19 other individual gene mutations.

In some rare cases of Joubert syndrome, an X-linked recessive pattern of inheritance has been seen. In these cases, the mutated gene is located on the X chromosome (one of the two sex chromosomes). Since males have only one X chromosome, one altered copy of the gene will cause the syndrome. Females have two X chromosomes; therefore, a mutation would have to occur in both copies of the gene to cause the disorder. Because it is unlikely that females will have two altered copies of this gene, males are affected by X-linked recessive disorders more frequently than females. A characteristic of

X-linked inheritance is that fathers cannot pass X-linked traits to their sons.

Acrocallosal syndrome-related disorders are extremely rare. Isolated individuals with similar symptoms have shown over 19 unique individual genetic mutations. Overall, approximately 50% of individuals with Acrocallosal syndrome (ACLS) Schinzel type-Joubert syndrome have mutations on one of the identified genes. However, in many families, this syndrome is not linked to any of the known mutations that cause this phenotype. For this reason, researchers believe that Acrocallosal syndrome, Schinzel type; Joubert syndrome; and related disorders demonstrate locus heterogeneity, meaning that there are multiple genetic locations for mutations that cause similar symptoms.

Demographics

Acrocallosal syndrome (ACLS) Schinzel type-Joubert syndrome and related disorders are extremely rare. Joubert Syndrome is estimated to affect 1 in 100,000 newborns. Reports of this disorder may occur within family lines or without any pattern. It affects both males and females. There are some reports of webbing of the fingers or toes (syndactyly) and relatedness (consanguinity) of the parents of affected children. However, affected children may also have unrelated, healthy parents and unaffected siblings.

Signs and symptoms

At birth, those with acrocallosal syndrome present the characteristic pattern of facial and limb malformations. Limb appearance ranges from minor webbing between the fingers or toes to near duplication of the hands or feet. Forehead prominence, increased distance between the eyes, and an enlarged head are the main features of facial appearance. X-ray tests will reveal the absence or incomplete formation of the corpus callosum, and the presence of any cysts within the cranium. The infant will usually display reduced muscle tone (hypotonia). This may lead to a drooling condition or feeding difficulties. Hypotonia can also contribute to a delay in growth and motor skills. Severe hypotonia is usually associated with a form of mental disability.

Progress and functioning during the first year of life is dependent upon the severity of the symptoms. There have been wide ranging variations reported. The degree to which symptoms affect each child may differ. Some children develop normally and will walk and talk within normal age limits; others may experience a delay or absence of certain motor activities. Intellectual disability may be mild to severe. Some children may develop

KEY TERMS

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Consanguinity—A mating between two people who are related to one another by blood.

Corpus callosum—A thick bundle of nerve fibers deep in the center of the forebrain that provides communications between the right and left cerebral hemispheres.

Hypertelorism—A wider-than-normal space between the eyes.

Hypotonia—Reduced or diminished muscle tone.

Polydactyly—The presence of extra fingers or toes.

Syndactyly—Webbing or fusion between the fingers or toes.

seizure disorders. The degree and progression of intellectual disability also varies by individual.

Diagnosis

The diagnosis of acrocallosal syndrome is based initially on the distinct pattern of facial and limb malformations. Computed tomography (CT), or a similar radiographic procedure, of the head is used to reveal the absence of the corpus callosum. Hand and foot x rays can be taken to confirm finger or toe abnormalities and to determine the extent of fusion, webbing, or duplication of the fingers and toes.

Prenatal diagnosis may not be possible due to the variability of the condition. However, prenatal ultrasound can detect duplication of the digits (polydactyly) and cerebral malformations. This may be especially informative for women who have affected children. There is a 25% risk of having another affected child.

Treatment and management

Beginning in infancy, physical therapy may assist in the development of motor skills and muscle tone. Surgery to remove extra fingers and to release fused fingers may improve movement and grasp, although the muscle tone may remain poor. Surgery to separate or remove affected toes may assist in walking and increase the comfort of footwear. Anti-epileptic therapy should be considered if a seizure disorder develops. Special-needs education

QUESTIONS TO ASK YOUR DOCTOR

- How many physical therapy sessions are required?
- Does my child's development appear delayed?
- What are the risks of surgery?
- What is the surgery's success rate in improving movement in the hands or feet?

may be required, depending on the level of intellectual impairment.

Prognosis

At present, there are no preventative measures for acrocallosal syndrome. The severity of symptoms and outcomes varies by individual. The quality of life for an individual with acrocallosal syndrome, Schinzel type is dependent upon the degree of intellectual disability and reduced muscle tone, rather than the extent of facial and limb malformations.

Acromegaly

Definition

Acromegaly is a rare condition caused by abnormally high amounts of human growth hormone (HGH). An organ in the brain known as the pituitary gland secretes this chemical. An average range of HGH is needed for normal growth and physical maturity in children. However, with acromegaly, there is an increased amount of HGH released, generally due to a tumor that forms in the pituitary gland. If left untreated, acromegaly can lead to numerous disabling conditions as well as a decreased lifespan.

Description

Acromegaly was first described in scientific detail by the French physician Pierre Marie. In 1886, Dr. Marie, along with his assistant, J.D. Souza-Leite, described two patients, designated cases I and II, and reviewed previously published case studies on patients III through VIII, all with acromegaly. These patients exhibited a rapid growth in their height as well as significantly enlarged hands and feet, a coarsening change in the appearance of their faces, frequent headaches, and a high incidence of visual problems. Dr. Marie believed that all of these problems were due to a defect in the patients' pituitary gland, a small glandular structure located in the middle of the brain.

While Dr. Marie was the first to state formally that a problem in the pituitary gland was responsible for the condition of acromegaly, the link between pituitary defects and acromegaly remained controversial for many

A photograph from 1898 showing the skeleton of an unknown person who had acromegaly. The person was 7 feet 6 inches tall. Acromegaly is a disorder that results from the production of excess growth hormone after the growth plates have closed. (Science Source)

years. It was not until 1909, when Dr. Harvey Cushing introduced the concept of hyperpituitarism in reference to acromegaly, that the association became generally accepted. Dr. Cushing believed that acromegaly caused the pituitary gland to secrete high levels of HGH, resulting in abnormal growth and, as time progressed, the development of acromegaly.

Acromegaly is a rare condition, with only about 1,000 cases per year in the United States among a total population of 330 million. If the condition presents before adulthood, it is also referred to as gigantism, because individuals grow much taller than usual because of their excessive levels of growth hormone. Some individuals with acromegaly may be as tall as seven or eight feet. Its striking consequence of excessive height has caused acromegaly to remain a fascinating disease among scientists, doctors, and the public. Besides potentially causing great height and unusual facial features, it is now known that acromegaly also causes serious conditions that can be life-threatening, such as

heart disease, respiratory disease, arthritis, neuromuscular problems, thyroid disease, and diabetes. Colon polyps are also more common in individuals with acromegaly, although it is not known whether colon cancer is more common. Other symptoms may include obstructive sleep apnea, a sleep disorder, as well as a deep voice, both of which are caused by soft tissue swelling and an enlarged tongue.

The genetics behind the majority of cases of acromegaly is still poorly understood. The most common cause of acromegaly is a benign (non-cancerous) tumor in the pituitary gland that secretes HGH. It is known that the tumor arises from cells in the pituitary gland, possibly due to a defect in the pituitary gland itself. Tumors larger than 1 centimeter in size can cause headaches and impede vision. The gene responsible for this tumor formation is unknown.

Even though the genetics of tumor formation in the pituitary gland leading to most cases of acromegaly are not yet known, there are other conditions that lead to acromegaly in which the genetic causes of the conditions are known. In a very rare condition called familial acromegaly, there is a gene on chromosome 11 believed to cause the formation and growth of an HGH-secreting tumor in the pituitary gland. Familial acromegaly is transmitted in an autosomal dominant pattern, which means that it has an equal chance of affecting both boys and girls in a single family. This condition can also cause tumors in other areas of the body besides the pituitary, including the parathyroid gland, which controls the amount of calcium in the bloodstream, and the pancreas, which regulates insulin in the body needs in order to process sugars.

Another uncommon condition causing HGH-secreting tumors in the pituitary gland is called multiple endocrine neoplasia-1, or MEN-1. This is an autosomal dominant condition characterized by a combination of pituitary, parathyroid, and pancreatic tumors. The gene for this condition has also been found on chromosome 11 and is known as the *MEN-1* gene. About half of the patients with this abnormal gene will eventually develop acromegaly.

Carney syndrome is a rare autosomal dominant disorder that can cause HGH-secreting pituitary tumors and acromegaly in about 20% of patients who have the syndrome. It is associated with a defective gene on chromosome 2. Besides acromegaly, people with Carney syndrome frequently have abnormal skin pigmentation, heart tumors, and tumors of the testicles and adrenal glands.

McCune-Albright syndrome is a very rare disorder that can cause acromegaly through HGH-secreting tumors in the pituitary. Other conditions associated with this syndrome include polycystic fibrous dysplasia (affecting bone growth, especially in the pelvis and long

bones of the arms and legs), abnormal skin pigmentation, early puberty, and thyroid problems. The gene for the syndrome, named *GNAS1*, is located on chromosome 20.

Demographics

Acromegaly is a very rare condition. It is estimated to occur in about 30–60 individuals per million people. Both males and females seem to be affected equally, and the condition more frequently presents when individuals are in their forties or fifties. These individuals do not grow taller, but there is an enlargement of the bones and a thickening of the soft tissues, such as of the tongue, the lips, and the heart. Some internal organs may enlarge, such as the spleen, the thyroid, the liver, and the kidneys. There also does not seem to be any difference in the secondary complications of acromegaly experienced by males and females. The condition has been recorded at all ages of life, from early childhood into old age. The frequency of chronic complications increases with age in both men and women.

Many cases of acromegaly are detected on an initial visit to a family physician, although some early or mild cases may be missed, causing a delay as long as years in the diagnosis. Some patients with acromegaly are initially diagnosed in specialty clinics, such as cardiology clinics or diabetic clinics, where they present with secondary problems caused by their acromegaly.

There is very little data on the differences of the occurrence of acromegaly among various ethnic and

racial lines. The few studies that have been done show no real difference among racial or ethnic groups, with acromegaly showing up equally in Caucasians, African Americans, and Asian Americans.

Signs and symptoms

The signs and symptoms of acromegaly can range from striking to almost unseen. The most visible signs of the condition are greatly increased height and coarse facial features that were caused by the abnormal growth of the facial bones. Another very noticeable feature is enlargement of both the hands and feet, which, as with the abnormal facial features, is the product of an excessive level of growth hormone and results in increased bone growth. The jaw may lengthen, causing malocclusion of the teeth as well as temporomandibular joint pain. Carpal tunnel syndrome is common, as is an early onset of osteoarthritis triggered by the condition. Individuals may notice that their rings no longer fit their fingers, and they may also need a larger shoe size, although successful treatment will decrease the size of the fingers and feet.

Other less visible, yet common, signs of acromegaly are increased sweating (hyperhidrosis), constant and at times debilitating headaches, visual disturbances, and increase in hair growth. Loss of sexual desire is often seen in both men and women. Amenorrhea, the cessation of menses (stopping of menstruation), is often a secondary condition associated with acromegaly in women. Females may also experience an abnormal milk flow

Acromegaly: pedigree analysis chart (Gale)

An acromegalous hand (left) beside and normal hand (right). This disorder causes uncontrolled growth, caused by excessive production of the growth hormone somatotrophin. (Biophoto Associates/Science Source)

from the breasts. Men may experience a lowered sexual drive or impotence. The pituitary tumor may press on the optic nerve, which may be revealed by testing such as magnetic resonance imaging.

There are further secondary complications of acromegaly that are not visible but can be life threatening. People with acromegaly are at greater risk for developing high blood pressure, cardiac disease, high cholesterol levels, arthritis and other degenerative diseases of the joints and spine, and diabetes. In addition, about 25% of individuals with this disorder experience hypertension. Acromegaly also increases the risk of other tumors, some of them cancerous, in other areas of the body, especially the breast, colon, and to a lesser degree, prostate.

With adequate treatment, especially early in the course of the condition, many of the secondary symptoms of acromegaly can be halted or even reversed. Less life-threatening complications, such as headaches, visual problems, and increased sweating, can be almost eliminated after adequate and timely treatment. More serious conditions, such as heart disease, high blood pressure, and diabetes, can be brought under control with treatment, although many times they cannot be totally eliminated.

Diagnosis

For most forms of acromegaly, there are no genetic tests yet available to diagnose the condition in newborns or before birth. Diagnosis is made by recognizing the clinical signs and symptoms previously described. Imaging tests may be used to identify the presence of a tumor in the pituitary. The patient's blood may be tested for elevated levels of insulin-like growth factor 1 (IGF1) or growth hormone. In certain very rare conditions, such as multiple endocrine neoplasia-1 and Carney syndrome, the genetics of the conditions are known and can theoretically be tested for. However, the conditions are so seldom encountered that unless a family member has the condition, genetic testing is usually not done until clinical signs and symptoms are apparent.

Treatment and management

The treatment and management of acromegaly have evolved over the past 100 years from crude surgery to genetically engineered medications. Today, through precise surgery and medications, a large percentage of patients with acromegaly can have their symptoms brought under control and in some cases totally cured.

KEY TERMS

Dopamine—A neurochemical made in the brain that is involved in many brain activities, including movement and emotion.

Hormone—A chemical messenger produced by the body that is involved in regulating specific bodily functions such as growth, development, and reproduction.

Somatostatin—A body chemical, known as a cyclic peptide, involved in the release of human growth hormone from the pituitary gland.

The goal of any therapy, be it surgery, medications, or radiation therapy, is a reduction in the level of HGH to levels seen in people without acromegaly. This goal may be achieved either through the removal or destruction of the tumor that is secreting the growth hormone, inhibition of HGH from the tumor, or blocking the effects of increased HGH on organs and other body systems outside the pituitary.

Surgical removal of the pituitary tumor is still the first treatment of choice for acromegaly. The rate at which a cure is achieved is determined by several factors, including the size of the tumor, whether or not it has spread outside the pituitary, and the level of HGH before the surgery. In patients with small tumors confined to the pituitary and exhibiting only moderately high HGH levels, the cure rate can be as high as 80% to 90%. In patients with larger tumors, especially those extending out of the pituitary, cure rates with surgery can be reduced to 40% to 60%.

Radiation therapy is often a second-line choice of treatment for acromegaly, especially in patients who have not achieved a cure with surgery. The treatment of acromegaly with radiation was used early on in the history of the condition, with the first report being written in 1909. Careful application of radiation can significantly reduce the size of pituitary tumors, subsequently decreasing high HGH levels. However, this decrease is often very slow, and it can take years for the HGH levels to drop to normal. Treatment with radiation can also have significant side effects, including damage to the pituitary gland itself, visual loss, and brain damage. Some studies have also suggested that treatment with radiation can lead to tumor formation in other areas of the brain.

The use of medications in the treatment of acromegaly has gained importance over the past few decades. The three key types of medications used to treat

acromegaly are somatostatin analogs, growth hormone receptor antagonists, and dopamine agonists. The somatostatin analog suppresses growth hormone and includes such drugs as octreotide, lanreotide, and pasireotide. Next, pegvisomant, a genetically engineered medication, is the GH receptor antagonist drug that may be used for treatment. Last, a dopamine agonist, such as bromocriptine, may be used to suppress GH. All of these medications are generally used in combination with surgery or radiation therapy.

Bromocriptine is known as a dopamine agonist and was one of the first pharmaceutical agents to be used to lower HGH levels in acromegaly. However, bromocriptine is not effective in the majority of cases, and consequently the medications octreotide and lanreotide have supplemented its use. These medications, both somatostatin analogues, decrease both the size of HGH-secreting pituitary tumors and the secretion of HGH itself. In multiple studies, they have been shown to normalize HGH levels in about 50% of cases and have been shown to shrink tumors in 45% of cases. The drawbacks to using both octreotide and lanreotide include multiple weekly dosing over a 12-month period, as well as acute side effects such as nausea, stomach pain, and diarrhea. Long-term use of these medications also results in an increased risk of developing gallstones.

Pegvisomant is a unique, recently developed genetically engineered HGH receptor antagonist. This medication does not decrease the amount of HGH secreted from pituitary tumors; rather, it desensitizes other organs of the body to the effects of the increased HGH circulating in the body. In medical trials, pegvisomant was well tolerated and resulted in significant symptomatic improvement. It is hoped that with a combination of surgery to decrease the tumor size and the use of an HGH antagonist like pegvisomant, both the acute and chronic debilitating symptoms of acromegaly can be greatly diminished, if not totally eliminated. The Pituitary Society reported in 2021 that patients with both acromegaly and diabetes, as well as a higher body mass, may need higher doses of medications such as pegvisomant. Some patients need combination therapy, and one option is a low dose or octreotide long-acting release medication or lanreotide, along with weekly dosages of pegvisomant.

Prognosis

The prognosis for patients with acromegaly who receive prompt treatment is good, although there are still possible complications. Patients who do not receive treatment, or those who receive it late in the course of the condition, have frequent and debilitating secondary complications as well as a greater chance for early death.

QUESTIONS TO ASK YOUR DOCTOR

- Are minimally invasive procedures available for removal of pituitary tumors?
- Is medication, rather than pituitary tumor surgery, an option?
- What risks are associated with medications?
- Based on my post-operative HGH level, what is my long-term prognosis?

There are only a few reliable studies examining the overall health benefits of treatment versus no treatment for patients with acromegaly. One study showed that those who received treatment before age 40 had a much better chance of not developing serious complications than those who were treated after age 40. Those who received earlier treatment had less chance of developing heart disease, high blood pressure, and diabetes, as well as other secondary complications of the condition.

Even with treatment, mortality rates for people with acromegaly are higher than those of the rest of the population. The principal causes of early death are cardiac disease, strokes, cancer, and respiratory failure. The level of HGH after treatment appears to offer the best data for predicting early mortality, with higher levels of post-treatment HGH corresponding to a greater, earlier mortality risk.

Adams-Oliver syndrome

Definition

Adams-Oliver syndrome (AOS) is a congenital condition that involves a combination of scalp defects (called aplasia cutis congenita) and a specific type of limb defect.

Description

Adams-Oliver syndrome is a genetic condition characterized by aplasia cutis congenita and abnormal outer limbs. People who have the syndrome often have malformed or missing hands, fingers, feet, and toes. Sometimes the abnormalities are noticeable in the fingernails and toenails; some people have fused fingers or toes. Congenital heart disease has also been reported in individuals with this condition. Several genes have been identified as probable causes of Adams-Oliver syndrome, but there are likely other genes that cause the syndrome that are not yet identified. The severity of problems among families with AOS varies a great deal.

Genetic profile

There have been both familial and non-familial cases of Adams-Oliver syndrome reported. Most genetic cases have been inherited in an autosomal dominant manner with the *ARHGAP31*, *RBPJ*, *DLL4* and *NOTCH1* gene mutations. Autosomal recessive and sporadic inheritance

forms have also been reported. These are associated with the *DOCK6* and *EOGT* gene mutations.

Autosomal dominant inheritance means that only one abnormal gene copy is required for the disorder to occur. For persons with a copy of the gene, the risk of passing it to their offspring is one in two, or 50%.

Autosomal recessive inheritance means that two defective gene copies must be inherited, one from each parent, for the disorder to be present. A person with only one gene mutation is a carrier for the disorder. Individuals who are carriers for the recessive type of Adams-Oliver syndrome do not have any symptoms (asymptomatic) and do not know that they are carriers unless they have a child with the syndrome. The likelihood that each member of a couple would be a carrier for a mutation in the same gene is higher in people who are related. When both parents are carriers for the recessive type of Adams-Oliver syndrome, there is a one in four chance (25%) in each pregnancy for a child to have the disorder. There is a 50% chance that a healthy-appearing child is a carrier of the mutation and a 25% chance that the child does not have the gene mutation.

A sporadic genetic disorder is one that occurs for the first time in a family. The disorder can either become inherited by subsequent generations in an autosomal manner or occur just once because of a chance mutation. Different mechanisms have been postulated to explain how the sporadic form of Adams-Oliver syndrome occurs. They include trauma, uterine compression, amniotic band sequence, vascular disruption, and a large blood clot in the placenta. Amniotic band sequence is a condition resulting from strands of the amnion membrane causing amputation of parts of the fetus. Vascular disruption is blockage of blood flow to a developing part or parts of the fetus. A large blood clot in the placenta could possibly block certain important blood vessels and interrupt blood supply to developing structures. Recently, Adams-Oliver syndrome has been hypothesized to occur as a result of abnormalities in small vessel structures that occur very early in embryo formation. The vascular anomaly could be the result of a genetic defect causing decreased stability of embryonic blood vessels in the presence of specific forces.

Researchers have identified several genes responsible for Adams-Oliver syndrome. These include:

- ***ARHGAP31* gene mutations.** The *ARHGAP31* is a Rho GTPase activating protein gene, which helps to regulate proteins that signal chemicals within cells. The chemicals associated with the *ARHGAP31* protein are critical for certain parts of an embryo's development, especially the skull, heart, and limbs. In people with Adams-Oliver syndrome, the mutated protein is too short, making it

KEY TERMS

Aplasia cutis congenita (ACC)—A group of disorders with different causes and a common characteristic of absence of skin in a defined area.

Congenital—Refers to a disorder that is present at birth.

more active. This decreases the signals to the cells involved in development and impairs them.

- ***DOCK6* gene mutations.** The *DOCK6* gene instructs a protein called guanine nucleotide exchange factor, which also helps activate GTPase proteins. *DOCK6* is important in development of fibers that extend from nerve cells during development of the skull, heart, and limbs. Mutations in the *DOCK6* gene alter the way skin develops on the top of the head and how bones of the feet and hands develop.
- ***EOGT* gene mutations.** The *EOGT* gene provides instructions to proteins that modify other proteins. The alterations in proteins affect cell processes and how genes produce proteins. These changes can affect development of tissues throughout the body. Researchers are still learning precisely how the *EOGT* gene mutation influences Adams-Oliver syndrome. However, they know that at least three mutations in this particular gene exist in people with the disease. The most common mutation leads to an abnormally short protein.
- ***RBPJ* gene mutations.** The RBP-J protein produced by the *RBPJ* gene is important to the Notch signaling pathway aiding how certain cells develop in an embryo. If the gene has mutations, the proteins cannot properly signal how skin on top of the head or bones in the hand and feet develop. These abnormal developments are common symptoms of Adams-Oliver syndrome.
- ***NOTCH1* gene mutations.** The *NOTCH1* gene makes a specific receptor protein that is involved in signaling the specialization of certain cells.

Demographics

Adams-Oliver syndrome was first described in 1945. There have been more than 125 cases reported in the medical literature. There does not appear to be any ethnic or sex difference in prevalence of this condition.

Signs and symptoms

Limb defects are the most common occurrence in Adams-Oliver syndrome, affecting about 84% of patients. The type of limb defect is usually asymmetrical

(not the same on both sides). The tendency to involve both sides of the body (bilateral) is seen more often in the lower limbs than the upper limbs. There is a wide range of severity in the limb defects, from minimal problems such as a small or missing finger or toenail (called nail hypoplasia), to the more severe absence of hands, feet, or lower legs. Other more moderate limb defects that have been reported include webbing (syndactyly) of the skin (cutaneous syndactyly) or bones (bony syndactyly) of the fingers or toes, claw-hand malformation (ectrodactyly), and brachydactyly (shortened fingers or toes). Brachydactyly is the most common limb defect in AOS.

Congenital cutis aplasia is the second most common problem and is present in about 75% of patients with Adams-Oliver syndrome. In 64% of patients with congenital cutis aplasia, there is also an underlying skull defect. More rarely, skull defects can be seen without scalp defects and may be mistaken for an enlarged soft spot (fontanelle).

Congenital heart defects have been reported to occur in 13% to 20% of patients with Adams-Oliver syndrome.

Many different types of vascular (involving the blood vessels) and valvular (heart valves) problems have been reported in these patients.

Other clinical features seen with AOS include short stature, kidney (renal) malformations, cleft palate, small eyes (microphthalmia), spina bifida occulta, extra (accessory) nipples, undescended testes, skin lesions, and neurological abnormalities. Intellectual disability is present in a few cases.

Diagnosis

Aplasia cutis congenita is a physical finding that has many causes. To determine whether an individual has Adams-Oliver syndrome clinically, all infants with aplasia cutis congenita should have a complete pregnancy and family history taken, as well as a complete medical evaluation. When possible, relevant family members should be examined for evidence of the condition. When aplasia cutis congenita is discovered at birth, the placenta should be evaluated. Physical examination of the affected infant includes evaluation of other related structures, specifically teeth, hair, other areas of skin, nails, and the central nervous system. Once this evaluation has been completed and a specific diagnosis of Adams-Oliver syndrome has been established or refuted, genetic counseling can be provided. Several different genetic tests are available for Adams-Oliver syndrome.

Prenatal diagnosis by ultrasound of the limb defects and possible other abnormalities associated with AOS is possible, but clinical confirmation of the diagnosis usually occurs after birth.

QUESTIONS TO ASK YOUR DOCTOR

- Does my child show signs of having a disorder related to AOS?
- At what age should my child start wearing corrective shoes?
- What type of full-body work up is recommended?
- Which family members should undergo genetic testing?
- What are the chances that I might have another child affected with AOS?

Treatment and management

The treatment for AOS is different for each individual and is tailored to the specific symptoms present. If leg-length discrepancy is present, corrective shoes that increase the sole for the affected leg to prevent scoliosis and ambulation difficulties can be worn. Orthopedic devices such as prostheses are sometimes recommended. Patients should be referred to a physician specializing in treating patients with limb defects early in life. Surgery for congenital defects and skin grafting for scalp defects may be necessary. (About 30% of patients required skin grafting in one study.)

Treatment

All children diagnosed with Adams-Oliver syndrome should have a thorough medical evaluation to check for possible heart abnormalities.

About 30% of patients in one study experienced a major hemorrhage from the scalp defect. Twenty percent of patients had local infection of the scalp defect. Treatment such as transfusion or antibiotic therapy may be required in these cases.

Special devices for writing or other activities may be necessary if hand malformations are present. Appropriate special-needs services are available for those with intellectual disability. Counseling and support related to limb deficiency issues are essential for coping. Support groups can provide valuable peer referrals and information.

Prognosis

AOS does not usually alter lifespan, although complications from associated abnormalities such as intellectual disability can cause problems. About 5% of the scalp defects that hemorrhaged severely were fatal. Rare cases of meningitis as a result of infection of the scalp

defect have been reported. Asymmetry of the limbs can interfere with their proper function and cause pain. Psychological issues relating to disfigurement are possible.

Clinical trials are experimental new drug treatments and procedures for a disease or disorder. Participation is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>.

Adaptive immunity

Our skin, saliva, and mucous are parts of the nonspecific immune system that serve to eliminate parasites,

perform phagocytosis (the process by which infected cells are engulfed and destroyed), and produce inflammation (the process used to defend the body from harmful or disease-causing agents). The non-specific immune system also aids in the development of adaptive and specific immune responses against infectious agents to which an individual has been exposed previously.

Adaptive immunity describes the specific defenses targeting foreign or infectious agents that have been encountered before. A key characteristic of the adaptive immune system is its ability to learn to recognize and attack pathogens (disease causing agents such as bacteria and viruses). Humans adapt to surroundings over time with specific immunity by selectively promoting the development of white blood cells and the products they make in response to specific threats. The body can use millions of combinations of cell surface or excreted proteins called antibodies, plus specialized cells to eliminate a toxic or infectious agent through specific immunity. The body develops specific immunity by using both humoral (antibody-mediated) and cell-mediated immune components over time.

Humoral Immunity, B cells, and Antibodies

The humoral immune system is also known as antibody-mediated immunity because it relies on the actions of white blood cells called B cells and the antibodies they make after maturing in the bone marrow. The antibodies are globular proteins made from several polypeptide chains with carbohydrate structures bound to them. There are several classes of antibodies, with IgG, IgM, IgA, and IgE antibodies in different proportions in different locations of the body; each antibody serves a slightly different functions from each other.

Antibody Clonal Selection

Clonal selection involves only those B cells whose surface-bound antibody-like protein can bind to a foreign invader in precise a lock-and-key-type fit. Those B cells with proteins that cannot bind do not participate. When a B cell is bound, activation begins. The B cell replicates and changes characteristics into antibody secreting, or plasma cells. The foreign invader that originally bound the B cell is called an antigen.

Antibody Functions in Adaptive Immunity

In neutralization, a large number of antibodies bound on the surface of a microbe or particle can block the invaders' access to their targets in the body. In complement-mediated killing, factors (collectively called complement) that can kill bacterial cells locate the bacteria due to the bound antibodies.

Adaptive immune system diagrammed from antigen presentation to activation of other immune cells. (Shutterstock/Designua)

Agglutination, or clumping together of multiple invaders through their bound antibodies, allows lethal cells to locate numerous linked invaders at once. Opsonization, also called enhanced attachment, is a process in which bacteria or other antigens are coated with opsonins, facilitating more efficient phagocytosis, or cell eating, by white blood cells. It is more efficient when many antibodies are bound to the surface of a microbe. Antibodies also attract white blood cells that kill parasites when they release lethal enzymes.

White blood cell functions in adaptive immunity

Cell-mediated immunity was discovered 50 years after antibodies were first identified. We know now that some functions of adaptive immunity are performed by one of several T cells, which leave the bone marrow and migrate to the thymus to mature, then around to the lymphatic tissues of the body. Virus- or other parasite-infected cells or cancer cells with foreign antigens exposed on their surfaces are the preferred antigens of cellular immunity.

Classes of T cells and their Products

In humoral immunity, T helper cells stimulate B cells to produce antibodies by releasing chemical signals called cytokines. T helper cells also act in cell-mediated immunity by binding antigens with their surface receptors. Usually, the antigen is a fragment of an invader that has been digested by an immune cell and then pushed to the outer surface of the cell. In addition to binding an antigen presented on the surface of the human cell, a chemical signal from the antigen-presenting cell causes only the bound T cell to multiply, become further specialized, and form memory T cells.

Cytokines made by T cells of the T helper 1 variety act to control cells of the cell-mediated immune system and T helper 2 cells produce cytokines that participate in the allergic response and in responding to parasites. Cytokines that transmit signals between white blood cells are called interleukins. As of July 2021, twenty-nine interleukins have been discovered, characterized, and named.

Cytotoxic T cells differentiate to cytotoxic T lymphocytes (CTLs) once exposed to cytokines from T helper cells. The CTLs then recognize foreign antigens on human cell surfaces and destroy the cells to eliminate virus-infected or cancer cells. Regulatory T cells suppress the activity of other T cells. They regulate inflammation, the autoimmune response, and transplant organ rejection. Since each of these functions is vitally important for health, this cell population is the subject of much research.

Antigen-presenting cells

Dendritic cells and activated macrophages are antigen-presenting cells that function in cellular immunity. Both engulf and digest invaders and then present bits of the invaders' molecules on their own surfaces, offering them as examples to the rest of the immune system. After taking up invaders, antigen-presenting cells migrate to lymphatic tissues. There, they encounter T cells with receptors ready to bind an antigen and to begin to multiply and mature.

Development of Immunologic Memory

Four to seven days after exposure to a foreign body, human sera (the clear liquid separated from coagulated blood that contains antibodies) will have measurable antibody titers, or relative units of IgM antibodies. IgG antibodies soon replace the IgM as titers peak in a couple of weeks. This is the first or primary response.

After a second exposure, weeks to decades later, the secondary or anamnestic response occurs. The humoral development is triggered by memory B cells that remain

in circulation from the first exposure until the second. When the memory B cells detect the second exposure, they give rise to plasma cells, which rapidly produce large quantities of antibodies against the invader rapidly and in large quantities. The intensity and speed of the secondary response prevent people from becoming sick a second time. That protection is due to our adaptive immunity.

T cell-mediated adaptive immunity functions mainly in cancer prevention. T cells undergo a maturation after the first exposure also. The secondary response upon re-exposure is also specific, fast, strong, and adaptive.

Adelaide-type craniosynostosis

Definition

Adelaide-type craniosynostosis is an autosomal dominant disorder that is characterized by premature

closing of certain bones in the skull, causing deformations in head shape and appearance of the face.

Description

Adelaide-type craniosynostosis is one of at least ten types of craniosynostosis caused by genetic abnormalities affecting the development of the fibroblast growth factor, transforming growth factor beta, and Eph/ephrin signaling pathways. The disorder is also called Muenke syndrome, FGFR3-associated coronal synostosis, Pro250Arg, and P250R mutation. The first of these terms honor Maximilian Muenke, German-American geneticist, who first described the condition in 1996. The last three designations indicate the gene at which the mutation causing the disorder has occurred, the *FGFR3* gene.

At birth, the human skull consists of a number of sections separated by narrow fissures. These fissures allow the skull to expand as the brain grows; they eventually grow together, forming the closed skull of a physically mature person. In cases of craniosynostosis, one or more fissures close prematurely, often with the result that other portions of the skull grow to a greater extent than usual. This unbalanced growth may result in the malformation of the head and the face. In the case of Adelaide-type craniosynostosis, uneven growth may be so minimal as to be almost undetectable, or it can be serious enough to produce significant malformations and the appearance of a ridge along the coronal suture, the fissure that runs across the skull from ear to ear. In addition to a misshaped head, other manifestations of the condition may be wide-set eyes and flattened cheekbones. Other physical conditions tend to be absent, thus explaining an alternative (and now discouraged) name for the disease, nonsyndromic coronal craniosynostosis. In about 5% of all cases of Adelaide-type craniosynostosis, growth of the head is significant enough to qualify as macrocephaly, but such growth is so modest as to be essentially absent in a quarter of all cases. Other physical manifestations of the disease include:

- short, crooked, or webbed fingers and toes in about 50% of all cases
- abnormally broad toes
- developmental delay in about one-third of all cases
- significant hearing loss in about 30% of all cases
- modest learning disabilities in about 20% of all cases
- less-than-average height in less than 5% of all cases

Genetic profile

Adelaide-type craniosynostosis is caused by a mutation on the fibroblast growth factor receptor 3 (*FGFR3*) gene, which is responsible for the production of a protein with the same name, fibroblast growth factor receptor 3.

KEY TERMS

Autosomal dominant—A genetic trait that is expressed when only a single copy of a gene is present.

Cartilage—A tough connective tissue attached to the ends of bones that may, early in the development of the body, be converted to bone.

CAT scan—Acronym for a computed axial tomography, a computerized x-ray examination of internal organs.

Coronal suture—A fissure between two bony plates in the skull that runs across the top of the head from one ear to the other ear.

Craniosynostosis—Premature closure of any one of the sutures of the skull.

Macrocephaly—Having an unusually large head.

Mutation—An alteration in the chemical structure of a gene.

Syndrome—A set of symptoms that suggest the presence of a disease or the possibility of contracting a disease.

The protein plays an important role in controlling the rate at which cartilage is converted to bone. The mutation responsible for Adelaide-type craniosynostosis occurs at position 250 in the *FGFR3* gene, resulting in the replacement of the amino acid proline by the amino acid arginine, thus accounting for another name for the condition, Pro250Arg, or more simply, P250A. This change in molecular structure inactivates the protein, removing a factor that slows down the conversion of cartilage to bone. Without this moderating factor, bone growth accelerates and skull segments on either side of the coronal suture close more rapidly than normal.

The mutation responsible for Adelaide-type craniosynostosis may either be transmitted as an autosomal dominant trait or it may appear as a *de novo* (new) mutation. Patterns of inheritance may also be unclear because of the possibility of reduced penetrance of the mutation. Reduce penetrance refers to the possibility that carriers of a mutant gene do not actually express symptoms of the disorder associated with that gene. In such a case, parents of a child with Adelaide-type craniosynostosis may appear to be less severely affected by the mutation.

Demographics

Adelaide-type craniosynostosis occurs in 1 out of about every 30,000 births, qualifying its listing by the Office of Rare Diseases of the National Institutes of

Health as a “rare disease.” An estimated 9,000 individuals in the United States have the condition at the present time. Adelaide-type craniosynostosis accounts for about 8% of all cases of craniosynostosis. Studies tend to suggest that the condition is somewhat more severe in females than in males.

Signs and symptoms

The characteristics of Adelaide-type craniosynostosis are very similar to those of other forms of craniosynostosis, primarily malformed head and face, such as ocular hypertelorism, ptosis or proptosis (usually mild), midface hypoplasia, and a highly arched palate. In fact, prior to Muenke’s discovery in 1996, the condition was misidentified as one or another form of craniosynostosis. Today, the only way to distinguish it from other types of craniosynostosis is through blood tests that identify a mutation in the *FGFR3* gene.

Diagnosis

Examination

As with all forms of craniosynostosis, visible examination of the skull and face are the first steps in diagnosis of Adelaide-type craniosynostosis. An enlarged skull (macrocephaly), malformed head, and/or misshapen facial features strongly suggest some form of the disease. Other physical evidence, such as shortened stature and malformed digits, may support this diagnosis, but are frequently not present.

Procedures

Visual evidence for the presence of Adelaide-type craniosynostosis is typically confirmed by a CAT scan, which confirms the presence or absence of prematurely closed sutures in the skull.

Tests

Unlike other types of craniosynostosis, the Adelaide type of the condition is identified conclusively and unambiguously entirely on the basis of a single blood test for the *FGFR3* gene. The presence of a mutation in that gene conclusively provides a diagnosis for the disorder.

Treatment and management

Treatment for Adelaide-type craniosynostosis depends on the severity of the patient’s condition and its prognosis. In many cases, the condition is so mild, with little or no effect on the patient’s physical or mental health, no treatment at all is necessary. In a few cases, some effort may be made to adjust the shape and appearance of the patient’s skull for cosmetic reasons, a step that can be taken with the

QUESTIONS TO ASK YOUR DOCTOR

- How do I know if my child has Adelaide-type craniosynostosis?
- What is the prognosis for a child with Adelaide-type craniosynostosis?
- What types of treatment are available for Adelaide-type craniosynostosis?
- Is it possible to predict whether my spouse (partner) and I are likely to have a child with Adelaide-type craniosynostosis in the future?
- What causes Adelaide-type craniosynostosis?

use of a supportive frame worn while the skull is still developing. In more severe cases, surgery may be required to re-open the prematurely closed coronal sutures. The primary reason for such surgery is to relieve pressure on the growing brain. In the absence of craniosynostosis, the skull is able to grow as the brain grows, providing sufficient room for the brain to reach its normal size. When sutures in the skull seal prematurely, however, intracranial pressures build up, potentially causing damage to the brain and possibly retarding mental growth. Early surgery may reduce the risk of later complications, such as hydrocephalus. If that condition does develop, additional surgery may be required.

Prevention

As with any genetic disease, it is not possible to eliminate the possibility of having a child with Adelaide-type craniosynostosis. However, it is possible for prospective parents to have a blood test that determines whether or not they carry copies of the mutant gene that is responsible for the condition. Partners can then decide whether or not they want to have children, based on the information obtained from such a test. Prenatal tests (amniocentesis or chorionic villus sampling) are also available to determine whether a fetus carries the mutant gene responsible for Adelaide-type craniosynostosis. Individuals with Adelaide-type craniosynostosis may wish to have genetic counseling to understand the risks associated with having children who may inherit the mutated gene. Siblings of affected individuals may also wish to have genetic counseling to understand the risks associated with having children who also carry the mutated gene.

Prognosis

The prognosis for Adelaide-type craniosynostosis varies widely. The condition may improve, may deteriorate, or may not change in severity.

Adenylosuccinate lyase deficiency

Definition

Adenylosuccinate lyase deficiency is a rare autosomal recessive metabolic disorder characterized by a number of nonspecific symptoms that may include psychomotor and mental disability, seizures, and autistic behavior. Common synonyms for the disease are adenylosuccinase deficiency,

KEY TERMS

Amyotrophy—Wasting of the muscles.

Autism—Abnormal brain development characterized by impaired social interaction and communication and by restricted and repetitive behavior.

Autosomal recessive—A genetic trait that appears only when two copies of a mutated gene are present.

Brachycephaly—A genetic condition characterized by a flattened skull.

Psychomotor—Pertaining to muscle functions that are controlled by the brain.

Purine—A nitrogen-containing organic compound whose basic molecular structure consists of two rings joined to each other.

Sign—An indication of disease, injury, or other physical problem that can be observed by someone other than the person experiencing these conditions.

Strabismus—Abnormal alignment of the eyes.

Symptom—An indication of disease, injury, or other physical problem reported by the person experiencing these conditions, but not by some outside observer.

succinylpurinemic autism, and the abbreviation ASL deficiency.

Description

Patients with ASL deficiency have a variable mixture of symptoms that include impaired psychomotor development, epilepsy, autistic features, feeding problems, and amyotrophy. (Amyotrophy is the medical term for muscle wasting.) Abnormal physical features may also be evident, including reduced head size, flattened head (brachycephaly), abnormal alignment of the eyes (strabismus), reduced upper lip, and low-set ears. The severity of these symptoms differs considerably from person to person, to the point that individuals with more moderate conditions may be able to live essentially normal lives.

ASL deficiency disorder is commonly divided into four subcategories. Type I is by far the most common and is characterized by poor muscle tone, severe mental disability, and epileptic seizures. Type II is characterized by impaired mental and visual development and poor hearing. Type III is characterized by muscle wasting and poor mental and physical development. Type IV is a mixture of types I and II.

QUESTIONS TO ASK YOUR DOCTOR

- What is the most recent research on the use of purine supplements for the treatment of ASL deficiency?
- Have any new palliative or therapeutic treatments been developed for use with ASL deficiency?
- Given the current condition of the patient, what is his or her prognosis?
- What support services are available for patients with ASL deficiency and their families?

Demographics

Fewer than 100 cases of the disorder have been unambiguously confirmed throughout the world. However, some authorities believe that a much larger number of cases have not been identified or have been misidentified because of confusion about signs and symptoms.

Signs and symptoms

ASL deficiency is caused by mutations in the gene responsible for the production of the enzyme adenylosuccinate lyase. The gene responsible for ASL deficiency occurs on chromosome 22 and many mutations have been found to be associated with the condition. The enzyme adenylosuccinate lyase is responsible for two essential steps in the synthesis of purine products in the body. Purines are nitrogen-containing organic ring compounds with a number of important functions in the body, one of which is the synthesis of nucleic acids, such as DNA and RNA. They are also involved in the conversion of energy into forms that can be used by the body, as signaling agents for a number of biochemical reactions, and as antioxidants that protect cells from carcinogenic agents. Adenylosuccinate lyase catalyzes two reactions in the synthesis of purines. The first is the conversion of succinylaminoimidazole ribonucleotide to aminoimidazole carboxamide ribonucleotide which is important for protein enzyme activity. The second is the conversion of adenylosuccinate to adenosine monophosphate (AMP) which is important for molecular bonding of RNA.

The precise manner in which this disruption produces the symptoms of ASL deficiency had not been determined as of 2015. The lack of adenylosuccinate lyase or its presence in an altered form does, however, result in the formation of two compounds that normally do not appear in the human body, succinylaminoimidazole

carboxamide riboside (SAICA riboside) and succinyladenosine. The presence of these substances in cerebrospinal fluid, urine, or (less commonly) blood serves as an unambiguous indication of the medical condition. It is believed that these substances are toxic and that their build-up leads to the associated neurological problems.

Diagnosis

Initial diagnosis of ASL deficiency is based on overall observations of a person's physical and mental features. Some indicators might be the presence of seizures, one's mental development, one's current characteristics, any muscular abnormalities, or other physical abnormalities. The condition can be unambiguously diagnosed only with the detection of SAICA in plasma, urine, or cerebrospinal fluid.

Treatment and management

No effective treatment is currently available for ASL deficiency.

Prognosis

The prognosis for ASL deficiency patients is generally poor, especially for those with Type I ASL deficiency. Most of these individuals die during infancy. Individuals with less severe conditions may do relatively well, however, and some have been able to live relatively normal lives well into adulthood.

Prevention

As with all genetic disorders, there are no preventative steps for ASL deficiency disorder. However, genetic counseling may be advisable.

Adrenoleukodystrophy

Definition

Adrenoleukodystrophy is a progressive condition that affects the adrenal glands, the glands atop the kidneys responsible for the production of adrenalin, and myelin, which insulates the nerves in the brain and spinal cord.

Description

Adrenoleukodystrophy (ALD) was first described in the early 1900s and was originally called Schilder-Addison disease. It is named for the different parts of the body that are affected; “adreno” refers to the adrenal glands, “leuko” is the Greek word for white (myelin is often called the white matter in the brain and spinal cord) and “dystrophy,” meaning impaired growth. Therefore, this disease primarily affects the adrenal glands and the growth of the myelin in the brain and spinal cord. There is a wide range in the severity of symptoms. ALD mainly affects males, but occasionally females have mild or moderate symptoms.

Causes and effects

ALD is caused by problems in the peroxisomes. The peroxisomes are tiny structures in cells that help break down large molecules of fats into smaller ones so that they can be used by the body. In ALD the peroxisomes cannot break down saturated fats with very long chain fatty acids (VLCFA). There are two types of problems that occur because the VLCFA are not broken down. First, because

the VLCFA cannot be broken down, they accumulate throughout the body, especially in the brain and the adrenal glands. Very high levels of VLCFA are also seen in the blood. The second type of problem occurs because the fats that are usually made when VLCFA are broken down are not produced. This is in part what happens in the adrenal glands and in the myelin.

The adrenal glands are located on top of each kidney in the abdomen. Part of the job of the adrenal glands is to use cholesterol (a sterol made in the body when VLCFA are broken down) to make a few different steroids—chemical combinations that form the basis of hormones, body acids, and anabolic agents. The steroids are used to help the body properly use sodium and potassium and to break down proteins, carbohydrates, and other fats. Some of these steroids are also involved with sexual development and function.

The insulation that surrounds the nerves is called myelin and is also affected by the VLCFA not being broken down. Myelin is made up of a number of different proteins and fats. Normally the VLCFA break down and produce lipids that make up part of the myelin. When the VLCFA cannot break down, the fats necessary to make the myelin are not made, and the myelin is abnormal. In addition, for reasons not well understood, there is also active breakdown of myelin, also known as demyelination.

Genetic profile

ALD is caused by a mutation in a gene called the *ALD* gene. Genes contain the instructions for how the body grows and develops before and after a person is born. The *ALD* gene makes a protein called ALDP (ALD protein). Different proteins put together make the tissues and organs in the body such as myelin. ALDP is important because it helps VLCFA get into the peroxisomes. When there is a mutation in the *ALD* gene, the ALDP is abnormal or not present at all. As a result, the VLCFA cannot get into the peroxisomes and the VLCFA accumulate in other places in the body.

Genes are organized on structures called chromosomes. Hundreds to thousands of genes are found on each chromosome. There are 46 chromosomes in each cell of the body. These are grouped into 23 pairs. The first 22 pairs are the same in both males and females. The 23rd pair is called the sex chromosomes; having one X chromosome and one Y chromosome causes a person to be male; having two X chromosomes causes a person to be female. People get one member of each pair from the mother’s egg and one member from the father’s sperm.

The *ALD* gene is located on the X chromosome. Since males only have one X chromosome, they only

have one copy of the *ALD* gene. Thus, when a male has a mutation in his *ALD* gene, he will have ALD. However, females have two X chromosomes and therefore have two copies of the *ALD* gene. If they have a mutation in one copy of their *ALD* genes, they may only have mild symptoms of ALD or no symptoms at all. This is because their normal copy of the *ALD* gene does make normal ALD protein. Females who have one copy of the *ALD* gene with a mutation and one normal copy are called carriers.

Inheritance

ALD is passed on through families by X-linked recessive inheritance. This means that affected males are related through females in the family and there are no males in the family that have passed ALD onto their sons. Females pass on one of their X chromosomes to their children—sons or daughters. For a female carrier, if her normal X chromosome is passed on, her son or daughter will be unaffected and cannot pass ALD onto their children. However, if the X chromosome with the ALD mutation is passed on, a daughter will be a carrier and the son would have ALD. Therefore, a female carrier has a 50% or one in two chance of having an unaffected child (son or daughter), a 25%, or one in four, chance of having a carrier daughter, and a 25% or one in four chance of having an affected son.

When males pass on an X chromosome, they have a daughter. When they pass on a Y chromosome, they have a son. Since the ALD mutation is on the X chromosome, an affected male will always pass the ALD mutation on to his daughters. However, when he has a son, he passes on the Y chromosome, and the son is not affected. Therefore, an affected male passes the *ALD* gene mutation on to all of his daughters, but none of his sons.

Demographics

ALD has been described in people from all different ethnic groups. Approximately 1 in 20,000 to 1 in 42,000 people have ALD.

Signs and symptoms

Adrenal insufficiency

Almost all individuals affected with ALD have problems with their adrenal glands not working properly. This is called adrenal insufficiency. These problems include sluggishness, weakness, weight loss, hypoglycemia, nausea, vomiting, darkening of the skin color, and mental changes. Because adrenal insufficiency can cause problems with regulating the balance of sodium and potassium in the body, a person can go into shock and a coma, which can be potentially life threatening. Since this

aspect of ALD is readily treatable, it is important to identify these patients in order to prevent these complications.

Types of ALD

There is a wide range in the severity of symptoms and age of onset of ALD. All different severities have been seen within the same family. Therefore, a family who has many mildly affected members could still have a more severely affected member. ALD is roughly divided into three different types according to severity and age of onset. However, some patients do not fall neatly into one of these categories and instead fall somewhere in between. Each type is given a different name, although all have mutations (changes in the genetic code) in the same gene and the same type of inheritance.

The most severe form of ALD is called childhood ALD. About 35% of people with ALD have this type. These children usually have normal development in the first few years of life. Symptoms typically begin between four and eight years of age. Very rarely is the onset before the age of three or after the age of 15. In some boys, the first symptom may be seizures. In other children, they become hyperactive and have behavioral problems that may initially be diagnosed as attention deficit disorder. Early signs may also include poor school performance due to impaired vision that is not correctable by eye-glasses. Although these symptoms may last for a few months, other more severe problems develop. These include increasing problems with schoolwork and deterioration in handwriting and speech. They usually develop clumsiness, difficulty in reading and comprehension of written material, aggressive or uninhibited behavior, and various personality and behavioral changes. Most of these boys have problems with their adrenal glands by the time their first symptoms are noticed.

A milder form of ALD called adrenomyeloneuropathy (AMN) usually has a symptom onset at the age of 20 or later. Approximately 40%–45% of people with ALD have this type. The first symptoms are typically a progressive stiffness and weakness in the legs. Problems with urination and sexual function may also develop. Symptoms slowly progress over many years. Less than 20% of men with AMN will develop significant brain involvement that leads to cognitive and behavioral problems that are severe and may cause a shortened lifespan. About 70% of men with AMN will have problems with their adrenal glands when other symptoms are first noticed.

A third type of ALD is called Addison disease and affects about 10% of all of those with ALD. In this condition, people do not have the neurologic symptoms

associated with ALD and AMN, but do have problems resulting from adrenal insufficiency. Symptoms typically begin between two years of age and adulthood. The first symptoms are often vomiting, weakness or coma. People with Addison disease may or may not have darker skin. Many who are initially diagnosed with Addison disease will later develop symptoms of AMN.

In female carriers, about 20% will develop mild to moderate progressive stiffness and weakness in the legs and sometimes problems with urination. Rarely do they develop adrenal insufficiency. Symptoms in women generally do not begin before middle age.

Diagnosis

When the diagnosis of ALD is suspected, a test called magnetic resonance imaging (MRI) is usually required. In this test, pictures of the brain are taken and the amount of white matter (myelin) in the brain is measured. In people with symptoms of ALD, there are usually characteristic changes in the white matter. An MRI can be helpful in making the diagnosis of ALD, but if changes are seen on MRI, it does not confirm the diagnosis of ALD. Changes in the white matter may only be seen after 1–2 years of age when the brain has matured.

A definitive diagnosis of ALD can be made by measuring the level of the VLCFA in the blood. In 99.9% of males with all types of ALD, the level of the VLCFA in blood is very high. This is diagnostic of ALD.

When ALD is suspected, testing should also be performed to measure the adrenal function. In 90% of boys with symptoms of ALD and 70% of men with AMN, the adrenal glands are affected.

Approximately 85% of female carriers will have higher than normal levels of VLCFA in their blood. However, 15%–20% of female carriers will have normal levels of VLCFA in their blood, which gives a “false negative” result. If a woman wants to be certain about her carrier status, genetic testing to look for a specific mutation in the ALD gene can be performed. This testing usually involves drawing a small amount of blood. Before a woman could have testing to determine her carrier status, a mutation in the ALD gene must have already been found in an affected member of the family. If a mutation in the ALD gene has already been found in another family member, testing on another child suspected on having ALD would be done to look at the mutation known to cause ALD in the family.

Treatment and management

When the diagnosis of ALD is made, an important first step is to measure the level of adrenal function. If

KEY TERMS

Adrenal insufficiency—Problems with the adrenal glands that can be life threatening if not treated. Symptoms include sluggishness, weakness, weight loss, vomiting, darkening of the skin and mental changes.

Central nervous system (CNS)—In humans, the central nervous system is composed of the brain, the cranial nerves and the spinal cord. It is responsible for the coordination and control of all body activities.

Leukodystrophy—A disease that affects the white matter called myelin in the CNS.

Myelin—A fatty sheath surrounding nerves in the peripheral nervous system, which helps them conduct impulses more quickly.

Peroxisomes—Tiny structures in the cells that break down fats so that the body can use them.

Very long chain fatty acids (VLCFA)—A type of fat that is normally broken down by the peroxisomes into other fats that can be used by the body.

there is adrenal insufficiency, treatment should be given by steroid replacement, which can prove to be lifesaving. Adrenal function should be tested periodically.

Early on, it was thought that reducing the VLCFA in a person’s diet would help reduce the symptoms of ALD. Although some VLCFA does come from diet, most of it is produced in the body. Therefore, altering the diet alone does not cure ALD.

Lorenzo’s oil

A film called *Lorenzo’s Oil* told an embellished account of a real life family who had a young son with ALD and their search to find a cure for him. A possible treatment was found and was named Lorenzo’s oil, after their son, Lorenzo. The Lorenzo’s oil therapy worked to reduce the level of VLCFA in the blood. The idea was that if the level of VLCFA could be reduced, perhaps it would cure or help the symptoms. After a number of years of use, Lorenzo’s oil unfortunately does not seem to be an effective treatment, at least in those with advanced signs and symptoms. Although it does reduce the level of VLCFA in blood, it does not seem to alter a person’s symptoms.

Bone marrow transplant

One promising treatment is bone marrow transplant. However, this is a potentially dangerous procedure that

has a 10%–20% rate of death. Information is available on a limited number of patients. In the very small number of patients who have had a bone marrow transplant, a few have had their condition stabilize and a few have even made slight improvements. However, all of these people had the bone marrow transplant at an early stage of their disease. This treatment does have drawbacks, including the fact that there are limited numbers of donors who are a suitable “match” and a significant chance that complications will develop from the transplant. Early data suggests that bone marrow transplant is most effective when it is performed at an early stage of the disease when abnormalities are first seen through MRI. Additional long term studies are necessary to determine the overall success of these procedures.

Other treatments

Research is being done with other treatments such as lovastatin and 4-phenylbutyrate, both of which may help lower VLCFA levels in cells, but more work is necessary to determine their effectiveness. Gene therapy, a possible method of treatment, works by replacing, changing, or supplementing non-working genes. Although different gene therapy methods are being testing on animals, they are not ready for human trials.

Other types of therapy and supportive care are of benefit to both affected boys and their families. Physical therapy can help reduce stiffness and occupational therapy can help make the home more accessible. Support from psychologists and other families who have been or are in a similar situation can be invaluable. Many men with AMN lead successful personal and professional lives and can benefit from vocational counseling and physical and occupational therapy.

Prenatal diagnosis

Prenatal testing to determine whether an unborn child is affected is possible if a specific ALD mutation has been identified in a family. This testing can be performed at 10–12 weeks gestation by a procedure called chorionic villus sampling (CVS), which involves removing a tiny piece of the placenta and examining the cells. It can also be done by amniocentesis after 14 weeks gestation by removing a small amount of the amniotic fluid surrounding the baby and analyzing the cells in the fluid. Each of these procedures has a small risk of miscarriage associated with it, and those who are interested in learning more should check with their doctor or genetic counselor. Couples interested in these options should have genetic counseling to carefully explore all of the benefits and limitations of these procedures.

QUESTIONS TO ASK YOUR DOCTOR

- How often should adrenal function be tested?
- What are the risks of bone marrow transplant?
- At what point would you recommend starting physical or occupational therapy?
- Do you recommend genetic testing?

An experimental procedure, called preimplantation diagnosis, allows a couple to have a child that is unaffected with the genetic condition. This procedure is only possible for those families in which a mutation in the *ALD* gene has been identified. Those interested in learning more about this procedure should check with their doctor or genetic counselor.

Prognosis

The prognosis for people with ALD varies depending on the type of ALD. Those diagnosed with childhood ALD usually have a very rapid course. Symptoms typically progress very fast, and these children usually become completely incapacitated and die within three to five years of the onset of symptoms.

The symptoms of AMN progress slowly over decades. Most affected individuals have a normal lifespan.

Agenesis of the corpus callosum

Definition

Agenesis of the corpus callosum is the complete or partial absence of the corpus callosum, the structure within the brain that connects the two hemispheres.

Description

Agenesis of the corpus callosum is a congenital anomaly occurring during the first trimester of pregnancy. During this time, the fetal brain is developing, and bundles of nerve fibers that create the corpus callosum are forming. This process may be interrupted if the mother is exposed to toxic substances or certain medications during pregnancy. Genetic abnormalities in the fetus may prevent the nerve fibers from growing correctly. In most cases, the exact cause of agenesis of the corpus callosum is unknown.

MRI images of the brain of a newborn, showing the typical appearance when there is agenesis of the corpus callosum. For example, the lateral ventricles are more widely separated. (Living Art Enterprises/Science Source)

In some people with agenesis of the corpus callosum, these nerve fibers are formed, but grow from front to back rather than from side to side. When the anomaly forms from front to back, groups of nerve fibers known as bundles of Probst form. These bundles stay within each hemisphere, never crossing the midline, and the two sides of the brain cannot share information. This lack of communication causes the symptoms of agenesis of corpus callosum.

The term “agenesis of the corpus callosum” usually refers to a complete absence of the corpus callosum. In some individuals, the corpus callosum is partially formed, and the condition is referred to as dysgenesis of the corpus callosum. There are two types of dysgenesis of the corpus callosum, partial and atypical. Partial dysgenesis occurs when the front, or anterior, portion of the corpus callosum does not form. In atypical dysgenesis of the corpus callosum, the rear, or posterior, portion of the corpus callosum is not formed.

The corpus callosum is not essential for life or for normal intellectual functioning. Many people who have agenesis of the corpus callosum as an isolated condition have no symptoms at all, and some may only experience mild difficulties with skills that require matching visual patterns. Since the two hemispheres of the brain cannot communicate, images seen by one eye cannot be connected to images processed by the other.

The more severe symptoms experienced by people with agenesis of the corpus callosum are most often caused by other brain malformations, chromosomal abnormalities, and genetic syndromes of which agenesis of the corpus callosum is only one component. Especially in children who have agenesis of the corpus callosum in addition to other brain malformations, the effects can be severe, including mental retardation, seizures, hydrocephalus, and impairment of motor functioning.

Agenesis of the corpus callosum often occurs along with other brain malformations, such as Arnold-Chiari malformation, Dandy-Walker malformation, and other defects of the midbrain. It may also be found in patients with defects of the size and shape of the brain, such as schizencephaly, lissencephaly, pachygyria, and hydrocephalus.

Individuals with anomalies of the formation of the forebrain, such as frontal encephalocele and holoprosencephaly, will usually have agenesis of the corpus callosum as well. In this case, the forebrain does not develop into two distinct hemispheres, and the corpus callosum does not form. These are severe birth defects and are usually incompatible with life.

Agenesis of the corpus callosum may occur as an isolated birth defect; in such cases, a genetic cause has not been identified. However, it often occurs as part of a syndrome. Agenesis of the corpus callosum has been associated with more than 30 inherited syndromes caused by chromosomal and single-gene anomalies and may result from prenatal exposure to anticoagulant medication during the first trimester of pregnancy.

Agenesis of the corpus callosum may also be known as absent corpus callosum, corpus callosum hypoplasia, ACC, CCA, callosal agenesis, or callosal dysgenesis.

Genetic profile

Agenesis of the corpus callosum is a component of many different genetic syndromes and chromosomal abnormalities, most of which are extremely rare.

Examples of autosomal malformation syndromes that include agenesis of the corpus callosum are:

- acrocallosal syndrome
- Andermann syndrome
- craniofacial dysmorphism-absent corpus callosum-iris colobomas-connective tissue dysplasia syndrome
- Fryns syndrome
- Joubert syndrome
- Larsen syndrome
- Miller-Dieker syndrome
- Rubinstein-Taybi syndrome

- Seckel syndrome
- Varadi-Papp syndrome

Agenesis of the corpus callosum is found in X-linked malformation syndromes such as:

- Aicardi syndrome
- Berry-Kravis and Israel syndrome
- Brooks syndrome
- CRASH syndrome
- Opitz-Kaveggia syndrome (FG syndrome)
- Proud syndrome
- Toriello-Carey syndrome
- X-linked hydrocephalus

Agenesis of the corpus callosum occurs more frequently in individuals with trisomies, such as trisomy 3, trisomy 13, trisomy 15, and trisomy 18. It has also been associated with chromosomal rearrangements, such as Wolf-Hirschhorn syndrome (del(4)(p16)).

Demographics

Researchers estimate the frequency of individuals affected with agenesis of the corpus callosum in the United States to be approximately 5.3%. It is more common in females than males, and is often seen in individuals with other brain malformations and as a part of many complex chromosomal and genetic syndromes.

Signs and symptoms

The symptoms of agenesis of the corpus callosum can range from virtually no difficulties to significant delays in reaching developmental milestones, mental retardation, and limited mobility.

Agenesis of the corpus callosum may be asymptomatic if occurring as an isolated brain malformation. With the increased use of imaging studies, many cases of absence of the corpus callosum are inadvertently discovered when a patient has a test to diagnose an unrelated condition. For many people with agenesis of the corpus callosum, however, symptoms of other clinical and genetic syndromes and brain malformations can be severe, especially in infants.

Symptoms of agenesis of the corpus callosum may include:

- seizures
- delays in reaching developmental milestones, such as sitting up, crawling, and walking
- intellectual disability
- poor hand-to-eye coordination
- impairments in auditory and visual memory

KEY TERMS

Autosomal—Pertaining to one or more of the 22 chromosomes that are not involved in determining gender.

Arnold-Chiari malformation—A congenital anomaly in which parts of the brain protrude through the opening in the base of the skull into the spinal column.

Bundles of Probst—Abnormally developed nerve fibers in the brain.

Congenital anomaly—A defect that is present at birth.

Computed tomography (CT) scan—A diagnostic imaging procedure in which x-ray and computer technology are used to generate slices or cross-sectional images of the body.

Dandy-Walker malformation—A congenital anomaly of the brain that causes a specific type of hydrocephalus.

Encephalocele—A congenital anomaly in which part of the brain is herniated through the skull.

Forebrain—The anterior of the front section of the brain.

Holoprosencephaly—A congenital anomaly of the front sections of the brain.

Hydrocephalus—The excess accumulation of cerebrospinal fluid within the skull.

Lissencephaly—Abnormality of the brain in which the surface is smooth, lacking the normal folds and grooves known as gyria.

Magnetic resonance imaging (MRI)—A diagnostic procedure that uses a combination of high powered magnets, radio frequencies, and computers to generate detailed images of structures within the body.

Pachygyria—Abnormality of the surface of the brain in which the gyria, or folds and grooves, in the surface of the brain are too large.

Schizencephaly—Abnormality of the brain in which there are deep ruts and clefts in the surface of the brain.

Trisomy—Three copies of an individual chromosome as opposed to the normal set of two chromosomes.

X-linked—Located on the X chromosome.

Although agenesis of the corpus callosum can be asymptomatic, it is considered a risk factor for neurological impairment. Agenesis of the corpus callosum may be suspected in children who have seizures, especially a specific type of seizures called infantile spasms. Agenesis of the corpus callosum may also be suspected in children with feeding problems, poor muscle control, and difficulties sitting, standing, and walking. It may be diagnosed later in children who experience other symptoms, such as frequent headaches or repetitive speech, in addition to seizures.

Diagnosis

Agenesis of the corpus callosum is diagnosed primarily by computed tomography (CT) scan and magnetic resonance imaging (MRI). MRI is the preferred imaging method for identifying abnormalities of the structures of the brain.

Agenesis of the corpus callosum may be diagnosed prenatally after week 20 of gestation, using prenatal ultrasound.

Treatment and management

There is no treatment for agenesis of the corpus callosum; however, the symptoms may be managed. Most

symptoms associated with agenesis of the corpus callosum are caused by other anomalies that occur along with the defect.

Symptoms, such as seizures, may be treated with anticonvulsant medications. Another common associated condition, hydrocephalus, may be treated by the surgical installation of a medical device called a shunt. A shunt relieves the pressure of excess fluid in the brain by draining that fluid away from the brain.

For infants and young children with agenesis of the corpus callosum and syndromes that include agenesis of the corpus callosum, early intervention programs may be helpful in assisting these children to reach developmental milestones. Other treatments, such as occupational therapy, physical therapy, and speech therapy, may help individuals improve deficits caused by the accompanying malformations.

Prognosis

The prognosis for individuals with agenesis of the corpus callosum varies widely. If agenesis of the corpus callosum occurs alone, the prognosis is usually excellent. Depending on the other associated birth defects and the

severity of the syndrome affecting the patient, intellectual disability, impaired neuromuscular functioning, and a shortened life expectancy may result. In rare cases, syndromes that may include agenesis of the corpus callosum are incompatible with life.

Aicardi syndrome

Definition

Aicardi syndrome is a rare genetic disorder that causes defects of the eyes and brain. It is believed to be an X-linked dominant genetic trait. The syndrome is named after Dr. Jean Aicardi, who first described it in 1965.

Description

Aicardi syndrome is an X-linked dominant genetic condition primarily found in females because males with the disease do not survive to birth. It is alternately called agenesis of the corpus callosum (ACC) with chorioretinal abnormality because of the associated abnormal

Brains with Aicardi syndrome (Gale)

formation of the connection between the right and left hemispheres of the brain (the corpus callosum) and abnormal development of the choroid and retinal sections of the eye.

The eye is composed of three layers: the sclera, the choroid, and the retina. The sclera is the tough, white outer coat of the eyeball; it is unaffected in individuals with Aicardi syndrome. The choroid is the middle layer of the eye. It serves to nourish the retina and absorb scattered light. The retina is the inner, light-sensitive layer of the eye. The retina receives the image produced by the lens and contains the rods and cones that are responsible for color vision. Both the choroid and the retina are abnormally formed in individuals affected with Aicardi syndrome.

Genetic profile

The location of the gene mutation responsible for Aicardi syndrome has been localized to Xp22.3. At or near this same locus is the gene responsible for microphthalmia with linear skin defects (MLS) and the gene responsible for Goltz syndrome. It is assumed that Aicardi syndrome is dominant and X-linked with near 100% fetal mortality in males. Nearly all of the cases of Aicardi syndrome are believed to result from *de novo* mutations (new mutations that occur after conception) since parents of affected individuals have normal chromosomes.

KEY TERMS

Absence seizure—A brief seizure with an accompanying loss of awareness or alertness.

Choroid—A vascular membrane that covers the back of the eye between the retina and the sclera and serves to nourish the retina and absorb scattered light.

Corpus callosum—A thick bundle of nerve fibers deep in the center of the forebrain that provides communications between the right and left cerebral hemispheres.

De novo mutation—Genetic mutations that are seen for the first time in the affected person, not inherited from the parents.

Focal seizure—A seizure that causes a brief and temporary change in movement, sensation, or nerve function.

Grand mal seizure—A seizure that causes a loss of consciousness, a loss of bladder control, generalized muscle contractions, and tongue biting.

Infantile spasms—The form of grand mal or focal seizures experienced by infants prior to the development of many voluntary muscular controls.

Post-ictal state—A period of lethargy, confusion, and deep breathing following a grand mal seizure that may last from a few minutes to several hours.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Retinal lacunae—Small abnormal cavities or holes in the retina.

Demographics

Approximately 4,000 individuals, predominantly female, have been diagnosed with Aicardi syndrome worldwide. Aicardi syndrome is not associated with any particular sub-populations. It appears with equal frequency in all races and across all geographies. Because it is an X-linked dominant trait, it is observed almost exclusively in females.

Signs and symptoms

Aicardi syndrome is characterized by abnormalities in the connection between the left and right hemispheres of the brain (the corpus callosum), infantile spasms in affected infants and seizures in older affected individuals, developmental delays, lesions and other abnormalities of

the eye, and possible other defects in the brain such as holes where healthy brain tissue should be (brain cysts) and an enlargement of the connecting cavities (ventricles) of the brain. It is these abnormalities of the brain, including the corpus callosum, that lead to the observable symptoms of seizures and developmental delays. Aicardi syndrome may also be complicated by brain tumors, benign tumors of the scalp (lipomas), and cancer of the blood vessels (angiosarcoma).

The onset of infantile spasms in individuals with Aicardi syndrome is generally observed between the third and fifth months of life. It is at this time that the final connections (neural synapses) are made in the developing human brain. These infantile spasms are a form of the full seizures that are experienced by older affected individuals. A seizure is the result of sudden abnormal electrical activity in the brain. This electrical activity can result in a wide variety of clinical symptoms including muscle twitches; tongue biting; fixed, staring eyes; a loss of bladder control resulting in involuntary urination; total body shaking (convulsions); and/or loss of consciousness.

There are several types of seizures. Focal, or partial, seizures are characterized by a brief and temporary change in movement, sensation, or nerve function. Examples of this type of seizure include drooling, head turning, eye movements, lip biting, or rhythmic twitching of muscles. Focal seizures usually cause no change in awareness or alertness. An absence seizure is a brief seizure with an accompanying loss of awareness or alertness such as a staring spell. Focal and absence seizures are types of petit mal seizures. A grand mal seizure is characterized by a loss of consciousness, a loss of bladder control, generalized muscle contractions, and tongue biting. Grand mal seizures are also followed by a period of lethargy, confusion, and deep breathing (post-ictal state) that may last from a few minutes to several hours.

Individuals affected with Aicardi syndrome also have vision problems including blindness. These vision problems are the result of abnormal development of the two inner layers of the eye (the choroid and the retina). The most common type of malformation in the eyes of individuals with Aicardi syndrome is the appearance of small cavities or holes in the retina (retinal lacunae). Instances of small eyes (microphthalmia) and missing structures of the eye (coloboma) are also common.

Diagnosis

Aicardi syndrome is generally first diagnosed between the ages of three and five months. It is at this age that the final connections in the brain are completed. Once these connections are completed in an affected individual, the individual will begin to have infantile spasms.

QUESTIONS TO ASK YOUR DOCTOR

- What supportive measures can we provide at home?
- How many feedings a day should be given?
- How often should vision exams be done?
- What are the risks and benefits of the medications that you recommend?

These spasms are akin to seizures in older children. Infantile spasms combined with defects of the retina and choroid of one or both eyes is sufficient evidence for the diagnosis of Aicardi syndrome. Magnetic resonance imaging (MRI) can confirm the brain malformations, including the absence of the corpus callosum. Prenatal diagnosis is not yet available, but connection to the Xp22.3 locus makes genetic testing for this dominant trait theoretically possible.

Treatment and management

Treatment of an individual with Aicardi syndrome generally consists of seizure management, vision treatment for those individuals born with sight or partial sight, and early and continuing intervention programs for developmental delays. Because of the severe neurological damage, many individuals are unable to chew and swallow and must be fed with pureed food. The most common medications for affected individuals are anticonvulsive drugs such as valproic acid (brand names: Depakene, Valproate, Valrelease), clonazepam (brand names: Klonopin and Rivotril), phenobarbital (available as a generic drug), and phenytoin (brand name: Dilantin).

Prognosis

Aicardi syndrome is lethal in males prior to birth. The prognosis in females varies on a case-by-case basis. The estimated survival rate is 76% at 6 years of age and 40% at 14 years of age. There has been a report of a surviving individual with Aicardi syndrome in her late forties. Most individuals with Aicardi syndrome are either born blind or will become blind. Developmental delays and intellectual disability ranging from mild to severe are seen in all individuals affected with Aicardi syndrome.

Paul A. Johnson

ALA dehydratase deficiency

Definition

ALA dehydratase deficiency is a very rare autosomal recessive type of porphyria. Porphyrrias are disorders caused by disruptions in the metabolic pathway by which a class of biochemicals known as porphyrins are converted to heme, the oxygen-carrying component of hemoglobin that gives blood its red color. The condition is also known as ALAD deficiency porphyria (ADP). It was first described in 1979.

Description

Heme is produced in a series of biochemical reactions that requires eight different enzymes, one of which is delta-aminolevulinic acid dehydratase, which catalyzes the second stage of this sequence (abbreviated as ALAD, for aminolevulinic acid dehydratase). More than ten possible mutations have been discovered within the gene responsible for the production of ALAD. When mutations occur in both alleles of the gene, ALA dehydratase deficiency disorder may develop.

Like other types of porphyria, neurological signs and symptoms are prominent. However, the descriptions of ADP for the very small number of individuals for whom data are available vary widely. In one case, an infant who contracted the disorder died at a young age. In another case, a 63-year-old man did not develop symptoms until late in life; his primary symptoms were then

KEY TERMS

Autosomal recessive—A genetic trait that appears only when two copies of a mutated gene are present.

Enzyme—A protein that catalyzes biochemical changes in the body without itself undergoing permanent change.

Heme—An organic molecule that contains a single atom of iron and is responsible for the oxygen-carrying ability of hemoglobin.

Neuropathy—A disorder of the peripheral nervous system.

Polyneuropathy—A disorder in which a number of nerves in the peripheral nervous system malfunction simultaneously.

Porphyria—Any one of a number of diseases, usually genetic in character, in which the conversion of porphyrins to heme is disrupted; usually associated with neurological problems.

Psychosis—A severe mental disorder that results in a distorted view of reality.

Sign—An indication of disease, injury, or other physical problem that can be observed by someone other than the person experiencing these conditions.

Substrate—A compound on which an enzyme works in a biochemical reaction.

Symptom—An indication of disease, injury, or other physical problem reported by the person experiencing these conditions, not by an outside observer.

severe polyneuropathy. Two German males experienced an onset of the disease in their teens and experienced neuropathy and, in one case, paralysis of the arms, legs, and respiratory system. In spite of these serious symptoms, both patients survived to live a somewhat satisfactory life for more than 20 years.

Genetic profile

Mutations in the *ALAD* gene cause a reduction in the amount of delta-aminolevulinic acid dehydratase in the bloodstream. Without this enzyme, the substrate on which it normally acts, delta-aminolevulinic acid (ALA), begins to accumulate. Excess ALA, a neurotoxin, is responsible for the neuropathies associated with the disease.

Demographics

Only one case of ADP has ever been diagnosed in the United States, and six more cases have been found in other countries: three in Germany, two in Sweden, and one in Belgium.

Signs and symptoms

In addition to the neuropathy associated with all forms of porphyria, patients with ADP may also experience abdominal pain, nausea, vomiting, constipation, diarrhea, urinary retention, weakness in the arms and legs, seizures, respiratory impairment, and, in extreme cases, psychoses.

Acute attacks of ADP may be triggered by a number of factors, including the ingestion of substances that stimulate the P-450 system, such as barbiturates and sulfonamides, psychological or physical stress, decreased caloric intake, and use of estrogen or progesterone products.

Diagnosis

Initial diagnosis of ALA dehydratase deficiency is based on a physical examination in which the physician looks for abdominal tenderness and neuropathy. Weakness of arms and legs may also be apparent. Confirmatory tests are based on urine samples in which the levels of ALAD are severely depressed (usually less than 5% of their normal concentrations) and levels of porphyrin are elevated. Elevated levels of other proteins, such as coproporphyrin III and zinc protoporphyrin IX, by as much as a factor of 100 are also common, although the reason for this phenomenon is not known.

Treatment and management

The most severe manifestations of an acute ADP attack can be mitigated by removing factors responsible for such attacks, such as increasing caloric intake, relieving physical or psychic stress, and avoiding use of chemicals involved in the P-450 cytochrome system. Long-term maintenance for the disease requires a high-caloric diet that includes a minimum of 300 g of glucose daily. For treatment of acute ADP attacks, heme replacement therapy can be instituted, in which hematin, a modified form of heme, is administered intravenously. Metalloporphyrins, synthetic compounds of a porphyrin with a metal such as copper, silver, or magnesium, can also be used to reduce neurological damage, although such agents are not successful in reversing existing neurological damage. A liver transplant was attempted as a way of treating ADP with a six-year-old Swedish boy, but the procedure was unsuccessful, and the boy died three years later.

QUESTIONS TO ASK YOUR DOCTOR

- Given the patient's current status, what is the likely prognosis for the disease?
- What steps should I take to reduce the conditions resulting from an acute attack of ADP?
- Where can I obtain additional information about ADP?

Although it is not possible to prevent the onset of ADP when a person has two copies of the damaged *ALAD* gene, it may be possible to avoid or reduce the severity of acute attacks. The patient should maintain a proper diet, high in calories; avoid physical and psychic stress; and avoid the ingestion of substances known to be associated with an ADP attack, such as certain drugs and hormone products.

Prognosis

Prognosis differs dramatically for patients with ADP, with some surviving many years after their original diagnosis and others surviving for only a short time. This differential prognosis may be the consequence of different genetic conditions leading to onset of the disease.

Alagille syndrome

Definition

Alagille syndrome is a genetic condition characterized by liver disease, characteristic facial features, heart murmurs or defects, vertebral changes, and eye changes, as well as a variety of less frequently noted features. Alagille syndrome is also called arteriohepatic dysplasia, cholestasis with peripheral pulmonary stenosis, syndromic hepatic ductular hypoplasia, and Alagille-Watson syndrome.

Description

Alagille syndrome is a rare condition occurring either sporadically or in an autosomal dominant pattern of inheritance. Approximately 90% of cases are caused by changes in the *Jagged1* gene on chromosome 20. However, the diagnosis of Alagille syndrome is based on clinical features and family history. Obtaining medical information about family members can be difficult, as some people with Alagille syndrome are so mildly affected or have such variable symptoms that the condition may go unrecognized. Prognosis depends on the extent of major organ involvement, especially of the liver, heart, and kidneys. Liver transplantation is needed in some cases. Prenatal testing is available to families in which a genetic change has been identified. The interpretation of this testing is limited by the variability of clinical features, even within the same family. People with the same genetic change can have a wide range of medical problems with varying degrees of severity. Alagille syndrome is named for Dr. Daniel Alagille (1925–2005) who specialized in treating childhood liver diseases. International Alagille Syndrome Awareness Day is observed on January 24 in honor of Dr. Alagille's birthday.

Genetic profile

Alagille syndrome occurs sporadically in 15%–56% of cases, but it has been noted to follow an autosomal dominant pattern of inheritance in some families. In sporadic cases, the gene change occurred for the first time in the affected individual, and neither parent had the same gene change. In autosomal dominant inheritance, multiple generations of a family are affected with the condition. In either case, people who have the genetic change have a

50% chance of passing the altered gene on to each of their children. Since the gene is dominant, passing on one copy of the gene is enough to cause symptoms. However, the condition exhibits variable expressivity, which means that different people with the condition may experience different features of the disease or different levels of severity. One explanation is that different changes in the gene may cause different features of the syndrome. However, even when family members all have the same genetic change, different features and degrees of severity can occur. In addition, the condition is not fully penetrant. Some people who have the gene mutation, due to an affected parent and child, do not show any features of the disease.

Changes in a gene called the jagged1 (*Jag1*) gene on the short arm of chromosome 20 have been shown to be the underlying defect in many patients. The *Jag1* gene encodes a cell surface protein that plays a role in the regulation of fetal development. The protein is active in many cell types and directs cells to their proper place in the embryo. Seventy to 75% of Alagille syndrome probands have had an identifiable change within this gene. Of that 70%, 6% have been shown using a laboratory technique called fluorescent in situ hybridization to have a small deletion of a piece of the short arm of chromosome 20 (20p), which includes the *Jag1* gene. A variety of other molecular changes in the gene have been detected by sequencing the gene. Thirty percent of people with the condition do not have an identifiable change in (*Jag1*). It is possible that there are other genes that cause the disease in these families.

Demographics

Alagille syndrome is rare, occurring in one in 70,000 to 100,000 live births. The condition affects males and females equally. Most patients with Alagille syndrome come to medical attention in the first four months of life because of jaundice, an enlarged liver, severe itching of skin, or multiple raised nodular areas on the skin.

Signs and symptoms

Liver manifestations

One of the most common and most serious symptoms of Alagille syndrome is liver disease, which occurs in 90% to 100% of patients and often leads to growth delay or failure as a result of malnutrition. Because there is a reduction in the number of bile ducts in the liver, there are elevated bile acids in the blood and limited bile excretion from the body, causing jaundice, pruritus (severe skin itching), and xanthomas (raised nodules on the skin, especially at skin creases or areas of friction). Some patients have mild or no liver problems, while others have progressive liver failure.

KEY TERMS

Amniocentesis—A procedure performed at 16 to 18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from it can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10 to 12 weeks of gestation. Under ultrasound guidance, a needle is inserted through either the mother's vagina or her abdominal wall, and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

First-degree relative—A parent, child, or sibling is a first-degree relative. First-degree relatives have one half of their genes in common.

Hemivertebra—A defect in which one side or half of a vertebra fails to form.

Proband—The person in the family who is affected by a genetic disorder and who brings the family to the attention of a healthcare provider.

Second-degree relative—Aunts, uncles, nieces, nephews, grandparents, grandchildren, and half-siblings are second-degree relatives. These individuals have one-quarter of their genes in common.

Spina bifida occulta—The failure of vertebrae to close into the neural tube without nerves protruding. This is most often asymptomatic.

Cardiac manifestations

Heart defects and murmurs have been noted in 85% to 95% of patients with Alagille syndrome. The most common type of defect is pulmonary artery stenosis, although other types of defects also occur. Many of these defects do not have clinical significance to the patient. However, complex and severe heart defects occur and are some of the more common causes of mortality in patients with Alagille syndrome.

Eye manifestations

One important diagnostic feature of Alagille syndrome is a particular eye finding called posterior embryotoxon. This is an anterior chamber defect of the eye caused by a prominent, centrally positioned Schwalbe ring. This feature

can be seen through a split lamp examination and does not affect vision. Since 56% to 90% of patients have this or other changes in the eye, including retinal pigmentary changes, an eye examination can aid in diagnosis.

Skeletal manifestations

A particular finding called a butterfly vertebra is associated with Alagille syndrome. The term refers to the appearance of the space around the vertebrae due to clefting or disruption of formation of a vertebra. There are usually no physical problems associated with this radiological finding. The frequency of butterfly vertebrae in this syndrome is uncertain, with estimates ranging from 33% to 93% in different studies. Other skeletal malformations are also noted in these patients, such as spina bifida occulta and hemivertebrae. Therefore, radiological examination of the spine may aid in diagnosis.

Facial manifestations

The occurrence of particular facial features has been noted in 70%–95% of patients with Alagille syndrome. The facial features include a prominent forehead, deep-set and widely spaced eyes, a pointed chin, and a straight nose with a bulbous tip. These features are more subjective, but they are some of the most consistent features of the diagnosis.

Other manifestations

Problems with the structure and function of the kidneys have been noted with an occurrence of 40% to 70% of patients. Symptoms are usually mild, but renal disease has caused mortality in severe cases. Mild delays in gross motor function have been noted in 16% of children, most of whom had severe organ disease. Intracranial bleeding has also been noted with increased frequency and is associated with mortality in this syndrome.

Diagnosis

The diagnosis of Alagille syndrome is based on clinical features and can be made by the presence of liver disease plus two of the other major features. An ultrasound of the liver can rule out other causes of liver disease, and a liver biopsy can determine whether there is a reduction in the number of bile ducts. However, this finding occurs in other conditions as well as Alagille syndrome, and the timing of the biopsy is important. Older patients are more likely to have fewer bile ducts than those under five years of age. An echocardiogram for heart defects, a radiological examination of the spine, blood tests for renal function, an ophthalmologic examination, and an examination of facial features are important diagnostic tools. A careful family history is also important in diagnosis. When a first- or second-degree relative has already been

QUESTIONS TO ASK YOUR DOCTOR

- How often should liver function tests be performed?
- Would you like to obtain a medical history from other family members?
- What is the likelihood of requiring a liver transplant?
- If a liver transplant is needed, would family members be considered as potential donors?

diagnosed with Alagille syndrome, the presence of even one feature of the condition may constitute a diagnosis.

Once a diagnosis has been made in an individual, the parents should undergo an evaluation for subtle features of the condition. If a parent is diagnosed, then evaluation for appropriate extended family members would be offered. A correct diagnosis is important, because there are other syndromes that exhibit similar liver disease, heart defects, and eye findings. These syndromes are inherited in different ways, so the recurrence risk for offspring and other family members may be different.

Two different types of genetic testing are used: fluorescence in situ hybridization (FISH), which detects the small percentage of patients who have a deletion of the entire gene, and sequencing, which looks at changes within the gene. If a genetic change is identified in the family, prenatal testing would be available through chorionic villus sampling or amniocentesis. However, the interpretation of this testing is difficult, because the presence of a gene change does not allow one to predict the severity of the condition or which medical problems may occur.

Treatment and management

Liver transplantation is needed in 15% to 20% of patients. Other treatments depend on which of the other features of the condition are present and the degree of severity. Repair of heart defects is another surgical treatment that is needed in some cases.

Clinical trials (experimental new drug treatments and procedures for a disease or disorder) may be available to people with Alagille syndrome. Participation is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding and some supported by private industry, are posted at <https://www.clinicaltrials.gov>.

Prognosis

Prognosis for Alagille syndrome is quite variable and depends on the degree of liver, heart, and kidney disease and the presence of intracranial bleeding. Overall, survival rates are 72% to 85%. The survival rate of those undergoing liver transplantation is 60% to 80%. There is currently no method to determine which patients will reach end-stage liver disease.

Albinism

Definition

Albinism is a collection of inherited conditions affecting melanin production that result in a lack of pigment in the hair, skin, and/or eyes. The conditions are broadly classified as either ocular albinism (OA), which primarily affects the eyes, or oculocutaneous albinism

(OCA), which affects the eyes, hair, and skin. Vision problems are associated with all types of albinism.

Description

Albinism results from one of several different inherited genetic defects in the body’s ability to produce or distribute melanin. Melanin is a photoprotective pigment that absorbs ultraviolet (UV) light from the sun to protect the skin from damage. Sun exposure normally increases melanin in the skin to produce a tan. Many people with albinism do not have melanin in their skin, so they burn in the sun. They may eventually develop skin cancer if they do not adequately protect themselves from sunlight. Some children with albinism may develop some pigmentation as they grow older. Some people with albinism have freckles or large blotches of pigmentation but are still unable to tan.

Because melanin gives color to the skin, hair, and iris of the eye, people with albinism typically have pale skin, white or pale yellow hair, and light blue or gray eyes. Lack of pigment in the iris can cause the eyes to appear pink or violet in some types of light, because light is reflected from the reddish part of the retina in the back of the eye. However, some people with albinism have hazel or brown eyes. Many people with albinism have vision problems, since parts of the retina and nerve connections between the retina and the brain do not develop correctly in the absence of melanin. Their eyes also are often very sensitive to light.

Genetic profile

Melanin production by the body is a complex process, involving multiple genes. Defects in these different genes cause different types of albinism. Although albinism is usually inherited, and the risk factor is a family history of the disorder, most children with albinism are born to parents with normal skin, hair, and eye color. This is because most types of albinism are autosomal recessive disorders. Autosomal means that the causative gene is located on one of the 22 chromosome pairs other than the X or Y sex chromosomes. Recessive means that two copies of a defective gene—one inherited from the mother and one from the father—are required for the appearance of symptoms. People who inherit one normal gene and one gene for albinism have no symptoms, because the normal gene provides for normal melanin production and distribution. However, such people are “carriers,” with a 50% chance of passing on the defective gene to each of their offspring. If both parents are carriers, there is a 25% chance of passing on both copies of a defective gene to each of their offspring, who will then have albinism. Therefore, albinism is more common in

Albinism

(i.e. Oculocutaneous Albinism)
Autosomal Recessive

Albinism: pedigree analysis chart (Gale)

smaller populations in which people intermarry. Although the different types of albinism may share many symptoms, they are distinguished by their specific genetic defect.

Ocular albinism

OA primarily affects the eyes, although individuals with OA may have lighter skin, hair, and eye color than other family members. OA1 or XLOA, sometimes called Nettlehip-Falls ocular albinism, is the most common type of OA. It is caused by mutations (changes) in the *GPR143* gene, which is located on the X chromosome. Therefore, unlike other types of albinism, it is a sex-linked recessive trait with inheritance that differs from the genetic profile described above. Males have only a single X chromosome, inherited from their mothers. A woman who has a defective *GPR143* gene on one of her two X chromosomes is a carrier. Although not herself affected by albinism, because of the normal gene on her other X chromosome, each of her offspring has a 50% chance of inheriting the defective gene. Her male offspring who inherit the gene will have albinism. Males with XLOA will transmit their *GPR143* mutation to all of

their daughters but to none of their sons, who inherit their Y chromosome instead.

With XLOA, melanosomes—the granules that produce melanin—do not develop correctly. The skin symptoms of XLOA are minor. Skin and eye colors are usually within the normal range. However, there is no coloring to the retina, and males with XLOA are born with persistent visual impairment.

Oculocutaneous albinism

OCA is the most severe form of albinism. There are four types of OCA, which are caused by mutations in one of four different genes. The types of OCA may be further classified into subtypes, depending on the specific mutations in the genes.

- OCA1 is caused by mutations in the *TYR* gene that code for the enzyme tyrosinase, which is required to convert the amino acid tyrosine into melanin. OCA1 is characterized by white hair, very light skin, and light-colored eyes. OCA1A is the most severe form, resulting in a total absence of pigment in skin, hair,

and eyes, extreme susceptibility to sunburn, and vision problems.

- OCA2 is caused by mutations in the *OCA2* gene and is less severe than OCA1. People with OCA2 commonly have creamy white skin and light blond to brown hair.
- OCA3 is caused by mutations in the *TYRP1* gene and causes milder vision abnormalities than other types of OCA. OCA3 includes rufous oculocutaneous albinism, which typically affects dark-skinned people.
- OCA4 is caused by mutations in the *SLC45A2* gene and has symptoms similar to OCA2.

Other albinism types

Certain other genetic disorders can cause albinism along with other symptoms or pathologies. Hermansky-Pudlak syndrome (HPS) is a rare type of albinism in most parts of the world but is common among people from Puerto Rico. The amount of pigmentation varies greatly. The skin can be creamy white, yellow, or brown. Hair may be white, pale yellow, or brown, but is always lighter than in the rest of the population. Eye color ranges from blue to brown. HPS is associated with bleeding and bruising problems, visual abnormalities, and other pathologies, such as lung and bowel diseases.

- HPS type 1 (HPS1) is caused by mutations in the *HPS1* gene.
- HPS2 is caused by mutations in the *AP3B1* gene.
- HPS3 is caused by mutations in the *HPS3* gene.
- HPS4 is caused by mutations in the *HPS4* gene.
- Other genes associated with HPS are *HPS5*, *HPS6*, *AP3B1*, *BLOC1S3*, *BLOC1S6*, and *DTNBP1*.

Certain rare complex disorders can cause localized or partial albinism:

- Chediak-Higashi syndrome causes patches of colorless skin throughout the body. It is caused by defective *LYST* genes that cause abnormal melanosomes.
- Tuberous sclerosis causes small areas of colorless skin.
- Shah-Waardenburg syndrome may involve a lock of hair on the forehead or no coloring to one or both irises. ABCD syndrome is an acronym for albinism, black locks of hair, cell migration disorder of the gut neurocytes (Hirschsprung disease), and deafness. Both Shah-Waardengurg and ABCD syndromes are autosomal recessive inherited disorders caused by mutations in the *EDNRB* gene that encodes the endothelin B receptor.
- Piebaldism is characterized by patches of white hair or lighter-colored skin blotches. Unlike other types of albinism, it is an autosomal dominant trait, meaning that symptoms are apparent in the presence of only one

Albino child in Sierra Leone, Africa. (Feije Riemersma/Alamy)

defective gene. That gene is either the *KIT* protooncogene or the *SNAI2* gene interfering with the development of melanocytes (the cells that produce melanin).

Demographics

Albinism affects people of all races and nationalities, but different types are more prevalent in certain populations. Some form of albinism affects 1 in 17,000 people in the United States. About one person in 70 carries a single defective gene for albinism but has no symptoms of the condition. The most common form of OA—ocular albinism type 1 (OA1) or X-linked ocular albinism (XLOA)—affects at least 1 in 50,000–60,000 males, but is extremely rare in females.

Worldwide, OCA affects 1 in 20,000 people. OCA types 1 and 2 (OCA1 and OCA2) are more common than types 3 and 4 (OCA3 and OCA4). The prevalence of OCA1 and OCA2 is about 1 in 38,000–40,000 in most populations. OCA2 is more prevalent in African Americans, some Native American groups, and in people from sub-Saharan Africa. OCA2 is estimated to affect 1 in 1,500–3,900 Africans and up to 1 in 10,000 African Americans. OCA3 occurs primarily in people from southern Africa. OCA4 affects about 1 in 100,000 in most populations but is more common among Japanese and Koreans. The persecution of people with albinism is a longstanding tragedy in some African countries.

Signs and symptoms

Eye problems

Lack of melanin causes abnormal development in the eye. For example, the iris, which normally acts as a filter, may let too much light into the eye. Communication

between the retina (the surface inside the eye that absorbs light) and the brain may also be altered. These abnormalities can cause visual impairments such as a lack of depth perception, sensitivity to light (photophobia), nearsightedness, farsightedness, or astigmatism (a curvature in the lens that makes it difficult to focus on objects). Other common effects include nystagmus (constant, involuntary eye movements) and strabismus (wandering eye or crossed eyes). Strabismus can interfere with depth perception. Some people with albinism have functional blindness.

Skin conditions

Albinism can cause absence of color to the hair, skin, or irises. Some people have skin and hair that is lighter than normal or patches of colorless skin.

Other rare symptoms

Rare forms of albinism may cause deafness or decrease the body's ability to fight infection. HPS can cause a variety of medical problems. For example, it may interfere with normal platelet function. Platelets are a component of blood required for clotting. People with this complication may have frequent nosebleeds, bleeding gums, easy bruising, or slow wound healing. Women may have heavy menstrual bleeding and excessive bleeding during childbirth. HPS can lead to a condition called granulomatous colitis, which causes abdominal cramps, intestinal bleeding, and diarrhea. Scarring of the lungs (fibrosis) can cause restrictive lung disease leading to fatigue and breathing problems. People with HPS may also have kidney disease.

Diagnosis

Albinism may be diagnosed by a careful examination of the hair, skin, and eyes, in combination with a family history of the disorder. In the past, doctors examined a sample of hair root with a procedure known as a hairbulb pigmentation test. They also tested hair for the presence of tyrosine to identify the type of albinism. However, these procedures have been replaced by genetic testing to determine the type of albinism. People can also be tested to determine if they are carriers of albinism genes. Amniocentesis at 16–18 weeks gestation can be used for prenatal testing when the disease-causing mutation(s) in the family are known. Chorionic villus sampling (CVS), which can be performed in the first trimester of pregnancy, examines the cells of the placental chorionic villi for genetic analysis; the villi are normal growths found in the placenta that have the same genetic material as the fetal cells. Also, clotting tests, platelet counts, and platelet examination may be used in the diagnosis of HPS.

KEY TERMS

Autosomal recessive—A gene located on a chromosome other than the X or Y sex chromosomes and carrying a trait that is not expressed unless the second copy of the same gene inherited from the other parent is also recessive or mutated.

Carrier—Having one abnormal gene for a trait, such as albinism, and one normal gene for the trait (a heterozygote), without signs or symptoms of the disorder but the possibility of passing the abnormal gene on to offspring.

Hermansky-Pudlak syndrome (HPS)—A rare form of albinism that can include other problems, such as blood clotting, and lung and bowel disorders; there are four types of HPS caused by defects in four different genes.

Iris—The colored ring between the cornea and lens of the eye that controls the amount of light entering through the pupil.

Melanin—A pigment produced in the body that gives color to the skin, hair, and eyes.

Melanosomes—Granules that produce melanin inside specialized cells called melanocytes.

Nystagmus—Involuntary rapid eye movements.

Ocular albinism (OA)—Forms of albinism that primarily affect the eyes.

Oculocutaneous albinism (OCA)—Forms of albinism that can affect the hair, skin, and eyes; there are several inherited forms of OCA that are caused by defects in different genes.

Retina—The light-sensitive membrane at the back of the eye that includes photosensitive rod and cone cells that convert the image from the lens into electrical impulses sent to the brain by the optic nerve.

Strabismus—Crossed eyes; improper eye alignment that interferes with binocular vision.

Tyrosine (Tyr)—The amino-acid precursor of melanin.

X-linked ocular albinism (XLOA)—OA1; the most common type of ocular albinism, which primarily affects vision in males.

An ophthalmologist may perform electroretinography to detect vision problems related to albinism. A visual evoked potentials test can also be useful. Ophthalmologists may be able to identify female carriers of the gene for XLOA by reduced pigment in their retinas.

QUESTIONS TO ASK YOUR DOCTOR

- What type of albinism does my child have?
- How did my child inherit albinism?
- Who in the family should have genetic testing for albinism genes?
- What information will we get from genetic testing?
- What treatments are available for my child's eye condition?
- What types of sun protection are needed?

Treatment and management

There is no treatment for replacing melanin. Eye problems resulting from albinism can be treated but not cured. Treatments vary, depending on the specifics and severity of the disorder, with the goal of relieving symptoms. Children with albinism may need extra support from family or a counselor. Many families find support groups helpful.

People with albinism must avoid sunlight or use sunscreen with sun protection factor (SPF) of 20 or higher. They need to wear protective clothing, hats or visors, and UV-protected sunglasses when outside. They should watch carefully for any changes in birthmarks or moles that could become cancerous.

Although bifocals and other corrective lenses are helpful for some people, these may not be able to compensate for severe development defects of the retina. Surgery may improve the appearance of people with strabismus. Eye muscle surgery may help reduce involuntary eye movements associated with nystagmus. However, surgery may not significantly improve vision. Before undergoing surgery, some doctors have children wear an eye patch in an attempt to strengthen the weaker eye. Children may require special educational accommodations, such as large-print textbooks.

People with HPS and bleeding disorders should notify their doctors and dentists. They should avoid aspirin, which can further reduce blood clotting. Some physicians recommend wearing a medical alert bracelet. People with HPS should not smoke to avoid exacerbating lung disease.

Prognosis

Most people with albinism adapt readily to their condition and live healthy, productive lives. Some activities

may be limited because of the inability to tolerate sunlight. People with severe vision impairment may not be able to drive. Albinism does not directly affect lifespan. It may increase the risk of skin cancer. Furthermore, lung disease or bleeding problems can shorten the lives of people with HPS.

Since albinism is inherited, and the genes have been identified, people with a family history of albinism should consider genetic counseling and possibly testing.

Alcoholism

Definition

Alcoholism is an alcohol use disorder characterized by chronic physical, psychological, and behavioral issues caused by the frequent and excessive use of alcoholic beverages. Intervening factors include emotional and physical dependence on alcohol; increased tolerance over time to the effects of alcohol; and withdrawal symptoms if the person stops drinking. Alcoholism is sometimes referred to as alcohol dependence. According to the National Institute on Alcohol Abuse and Alcoholism (NIAAA), 14.5 million adults ages 18 years and older in the United States had an alcohol use disorder in 2019.

Description

Alcoholism is a complex behavioral problem as well as a medical disorder. It often involves the criminal justice system as well as the fields of medicine and other helping professions. Its emergence in an individual's life is affected by a number of variables ranging from age, weight, sex, and ethnic background to a family history of alcoholism, peer group use of alcohol, occupation, religious preference, and many other categories. Moreover, persons diagnosed with alcoholism may demonstrate considerable variety in their drinking patterns, their age at the onset of the disorder, and the speed of its progression. It is very important for people who are alcoholics to accept treatment, especially in the face of a recent study that revealed the numbers of deaths from alcohol increased significantly between 1999 and 2017. In a study by Aaron M. White and colleagues, the researchers used death certificates to analyze causes of death. They listed deaths as alcohol-related if an alcohol-induced cause was either an underlying cause or one of multiple causes

of death. The researchers found that alcohol-related deaths doubled from 35,914 in 1999 to 72,558 in 2017. They also found that nearly 3% of about 2.8 million deaths in the United States were alcohol-related. About half of these deaths involved liver diseases or overdoses from alcohol and/or other drugs. The highest rates of alcohol deaths were found among men ages 45 to 74 and non-Hispanic American Indians or Alaska Natives. The greatest annual increase, however, was found among non-Hispanic white females.

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), distinguished between alcohol dependence and alcohol abuse, largely on the basis of the compulsive element in dependence that is not present in abuse. However, the newer fifth edition, DSM-5, integrates the two disorders into a single diagnosis called alcohol use disorder (AUD), with mild, moderate, and severe sub-classifications. Alcoholism is a severe alcohol use disorder. Some psychiatrists differentiate between so-called primary alcoholism, in which the patient has no other major psychiatric diagnosis, and secondary alcoholism, in which the problem drinking is the patient's preferred way of medicating symptoms of another psychiatric disorder, such as depression, schizophrenia, post-traumatic stress disorder, or one of the dissociative disorders. Experts in other branches of medicine tend to emphasize patterns of, and attitudes toward, drinking in order to distinguish between the non-problematic use of alcohol and alcohol abuse or dependence. Classification is typically based on the following five categories:

- **Social drinkers.** Individuals who use alcohol in minimal to moderate amounts to enhance meals or other social activities. They do not drink alone.
- **Situational drinkers.** These people rarely or never drink except during periods of stress. They are far more likely to drink alone than social drinkers.
- **Problem drinkers.** These individuals drink heavily, even when they are not under overwhelming stress. Their drinking causes some problems in their lives (e.g., DUI arrests), but they are capable of responding to warnings or advice from others.
- **Binge drinkers.** This type of drinker uses alcohol in an out-of-control fashion at regular intervals. The binges may be planned in advance. This pattern has long been a problem on many college campuses.
- **Alcoholic drinkers.** These are drinkers who have no control of any kind over their intake, and they find that their lives are unmanageable.

Other factors have complicated definitions of alcoholism in the United States, including the increasing tendency to combine alcohol with other drugs of abuse,

Alcohol use disorder. (Shutterstock/solar22)

sometimes called cross-addiction, and the rising rates of alcohol abuse and dependence among adolescents.

Risk factors

According to the NIAAA, the risk for developing alcoholism seems to run in families. Genetics and lifestyle behaviors are both factors. The NIAAA says that genetics is responsible for about 60% of alcohol use disorders. Another causal factor is the early use of alcohol, and the NIAAA says that among individuals ages 26 years and older, people who started drinking before age 15 are greater than five times more likely to have an alcohol use disorder in adulthood, compared to individuals who did not start drinking until age 21 or older. Some mental health conditions also increase the risk for alcohol problems, according to the NIAA, particularly depression, post-traumatic stress disorder, and attention deficit hyperactivity disorder (ADHD). In addition, individuals who suffered childhood traumas are at risk for alcoholism in adulthood. Socializing patterns, the

amount of stress in a person's life, and the availability of alcohol are all factors that may increase the risk for alcoholism. In general, more men than women are alcohol dependent. Alcohol problems are highest in the 18-to-29 age group and lowest among adults aged 65 years and older.

Demographics

The World Health Organization (WHO) estimates that in 2018, three million people worldwide died because of their harmful use of alcohol, or about 4% of all deaths globally. In addition, the WHO reported that the use of alcohol in a harmful manner was a factor in more than 200 injury and disease conditions. In the United States, a major epidemiologic study on more than 36,000 subjects by Bridget F. Grant and colleagues revealed that the 12-month prevalence of alcohol use disorder was 14%, and the lifetime prevalence was 29%. The highest prevalence was seen in white males and Native Americans, as well as those at the lowest income

levels. The NIAAA reports that most people are never treated for their alcohol issues.

Alcohol use by persons under age 21 is an important public health concern. According to the NIAAA, in 2019, 14.1 million adults ages 18 years and older (about 6% of that age group) had an alcohol use disorder. Drinking is also an issue among adolescents; for example, in 2019, 414,000 adolescents ages 12 to 17 years old (about 2% of that age group) had an alcohol use disorder. In the United States, alcohol is the most commonly used and abused drug among youth. Although drinking under the age of 21 is against the law, people ages 12 to 20 years drank nearly 9% of all the alcohol consumed in the United States in 2016, based on research by Raimee H. Eck and colleagues.

Some women are alcoholics, and many women in the United States consume alcohol. In fact, in some cases, alcohol problems are greater in women than in men. According to the Centers for Disease Control and Prevention (CDC), nearly half of all adult females in the United States reported drinking alcohol in the past 30 days. In addition, about 13% of adult women are binge drinkers, consuming five drinks per binge on four occasions each month. Nearly a third (32%) of female high-school students consumed alcohol in 2019, which was greater than the rate among male high-school students (26%). Further, binge drinking was more common among female teenagers (15%) than male teenagers (13%).

One major concern is that many women drink alcohol during pregnancy. An estimated 20% of pregnant American women had at least one drink during the first trimester of their pregnancy in the period 2015 through

2018, according to Lucinda J. England, MD and colleagues. Further, about 5% of pregnant women reported consuming alcohol in their second or third trimester of pregnancy. This research was based on information provided by more than 3,000 pregnant women ages 12 to 44. This news is disturbing, because physicians urge pregnant women to consume no alcohol during pregnancy. Alcohol consumption during pregnancy puts their babies at risk for fetal alcohol spectrum disorders (FASDs).

Studies of female alcoholics indicate that women are at higher risk than men for serious health problems related to alcoholism. Because women tend to metabolize alcohol more slowly and have a lower percentage of body water and a higher percentage of body fat than men, they develop higher blood alcohol levels than men at a given amount of alcohol per pound of body weight.

At the other end of the age distribution, alcoholism among the elderly appears to be under-recognized. One-third of older alcoholic persons develop a problem with alcohol in later life, while the other two-thirds grow older with the medical and psychosocial consequences of early-onset alcoholism. Confusion and other signs of intoxication in an elderly person are often misinterpreted as side effects of other medications or dementia. In addition, the effects of alcohol may be increased in elderly patients because of physiological changes associated with aging. The elderly are at higher risk than younger people for becoming dependent on alcohol, because their bodies do not absorb it as efficiently; for example, a 90-year-old who drinks the same amount of alcohol as a 20-year-old (of the same sex) will have a blood alcohol level 50% higher.

(Gale)

Signs and symptoms

The symptoms of alcohol intoxication often include talkativeness and a positive mood while the drinker's blood alcohol level is rising, with depression and mental impairment occurring when it is falling. Blood alcohol concentration (BAC) produces the following symptoms of central nervous system (CNS) depression at specific levels:

- 50 mg/dL: feelings of calm or mild drowsiness
- 50 to 150 mg/dL: loss of physical coordination. The legal BAC for drivers in most states is 100 mg/dL or lower.
- 150 to 200 mg/dL: loss of mental faculties
- 300 to 400 mg/dL: unconsciousness
- Over 400 mg/dL: may be fatal.

The symptoms of long-term heavy consumption of alcohol may take a variety of different forms. In spite of a long history of use for “medicinal” purposes, alcohol is increasingly recognized to be toxic to the human body. It is basically a CNS depressant that is absorbed into the bloodstream, primarily from the small intestine. Regular consumption of large amounts of alcohol can cause irreversible damage to a number of the body's organ systems, including the cardiovascular system, the digestive tract, the central nervous system, and the peripheral nervous system. Heavy drinkers are at high risk of developing stomach or duodenal ulcers, cirrhosis of the liver, and cancers of the digestive tract. Many alcoholics do not eat properly and often develop nutritional-deficiency diseases as well as organ damage.

In addition to the physical symptoms, most alcoholics have a history of psychiatric, occupational, financial, legal, or interpersonal problems. Alcohol misuse is the single most important predictor of violence between domestic partners as well as intergenerational violence within families. Alcohol is also involved in deaths caused by drunken driving. The National Highway Traffic Safety Administration (NHTSA) reported that 10,142 people died as the result of alcohol-impaired collisions in 2019. All states have passed stricter laws against alcohol-impaired driving. These laws include such provisions as immediate license suspension for the first DWI arrest and lowering the legal blood alcohol limit to 0.08 g/dL for adults and 0.02 g/dL for drivers under age 21. Penalties for repeated DWI citations include prison sentences; house arrest with electronic monitoring; license plates that identify offending drivers; automobile confiscation; and putting a special ignition interlock on the offender's car.

Diagnosis

The diagnosis of alcoholism is usually based on the patient's drinking history, a thorough physical examination, laboratory findings, and the results of psychodiagnostic assessment.

Examination

A physician who suspects that patients are abusing or are dependent on alcohol should give them a complete physical examination with appropriate laboratory tests, paying particular attention to liver function and the nervous system. Physical findings that suggest alcoholism include head injuries after age 18; broken bones after age 18; other evidence of blackouts, frequent accidents, or falls; puffy eyelids; a flushed face; alcohol odor on the breath; shaky hands; slurred speech or tongue tremor; rapid involuntary eye movements (nystagmus); enlargement of the liver (hepatomegaly); hypertension; insomnia; and problems with impotence (in males). Severe memory loss may point to advanced alcoholic damage to the CNS.

Tests

Several laboratory tests can be used to diagnose alcohol abuse and evaluate the presence of medical problems related to drinking. These tests include:

- Complete blood cell count (CBC). This test indicates the presence of anemia, which is common in alcoholics. In addition, the mean corpuscular volume (MCV) is usually

high in heavy drinkers. An MCV higher than 100 fL suggests alcohol abuse.

- Liver function tests. Tests for serum glutamine oxaloacetic transaminase (SGOT) and alkaline phosphatase can indicate alcohol-related injury to the liver. A high level (30 units) of gamma-glutamyltransferase (GGT) is a useful marker, because it is found in 70% of heavy drinkers.
- Blood alcohol levels.
- Carbohydrate deficient transferrin (CDT) tests. This test should not be used as a screener, but it is useful in monitoring alcohol consumption in heavy drinkers (those who consume 60 grams of alcohol per day). When CDT is present, it indicates regular daily consumption of alcohol.

The results of these tests may not be accurate if the patient is abusing or dependent on other substances.

Procedures

Since some of the physical signs and symptoms of alcoholism can be produced by other drugs or disorders, screening tests can also help to determine the existence of a drinking problem. There are several assessment instruments for alcoholism that can be either self-administered or administered by a clinician. The so-called CAGE test is a brief screener consisting of four questions:

- Have you ever felt the need to *cut down* on drinking?
- Have you ever felt *annoyed* by criticism of your drinking?
- Have you ever felt *guilty* about your drinking?
- Have you ever taken a morning *eye opener*?

One “yes” answer to the questions above should raise a suspicion of alcohol abuse; two “yes” answers are considered a positive screen.

Other brief screeners include the Alcohol Use Disorder Identification Test, or AUDIT, which also highlights some of the physical symptoms of alcohol abuse that doctors look for during a physical examination of the patient. The Michigan Alcoholism Screening Test, or MAST, is considered the diagnostic standard. It consists of 25 questions; a score of five or higher is considered to indicate alcohol dependency. A newer screener, the Substance Abuse Subtle Screening Inventory, or SASSI, was introduced in 1988. It can be given in either group or individual settings in a paper-and-pencil or computerized format. The SASSI is available in an adolescent as well as an adult version from the SASSI Institute.

Some brief screeners may be inappropriate for widespread use in some subpopulations because of ethnic and sex bias. The CAGE questionnaire has often yielded inaccurate results when administered to African American

men and Mexican American women. The AUDIT does not appear to be affected by ethnic or gender biases. Another study of the use of alcohol screening questionnaires in women found that the AUDIT was preferable to the CAGE questionnaire for both African American and Caucasian women.

Treatment and management

Because alcoholism is a complex disorder with social and occupational as well as medical implications, treatment plans usually include a mix of several different approaches. The following key issues are usually considered in determining which treatment option is appropriate:

- Severity of the problem and evidence to suggest other mental health problems (e.g., depression, suicide attempts).
- staff credentials of those treating the child or teen, and what forms of therapy (e.g., family, group, medications) are to be used
- Nature of family involvement.
- How education is to be continued during treatment.
- If an in-patient program is necessary, what length it should be.
- What aftercare is to be provided following discharge.
- What portion of treatment is to be covered by health insurance, and what needs to be paid out of pocket.

Traditional

Most alcoholics are treated with a variety of psychosocial approaches, including regular attendance at Alcoholics Anonymous (AA) meetings, group therapy, marital or family therapy, social skills training, relapse prevention, and stress management techniques. Insight-oriented individual psychotherapy by itself is ineffective with the majority of alcoholics. Some individuals need to be hospitalized to detoxify from alcohol in a safe manner

The most effective psychosocial treatments of alcohol dependence incorporate a cognitive-behavioral approach. Relapse prevention utilizes cognitive-behavioral approaches to identifying high-risk situations for each patient and restructuring his or her perceptions of the effects of alcohol as well as of the relapse process. Network therapy, which combines individual cognitive-behavioral psychotherapy with the involvement of the patient’s family and peers as a group support network, is a newer approach to alcohol dependence.

Drugs

Most drugs that are used to treat alcoholism fall into one of two groups: those that restrain the desire to drink by producing painful physical symptoms if the patient does drink, and those that appear to reduce the craving for

alcohol directly. Several medications in the second category were originally developed to treat addiction to opioid substances (e.g., heroin and morphine). Although medications have been proven effective, the NIAAA reports that only 4% of individuals with alcohol use disorder took one of these medications in 2019.

ALCOHOL-SENSITIZING MEDICATIONS. The most commonly used alcohol-sensitizing agent is disulfiram (Antabuse), which has been used since the 1950s to deter alcoholics from drinking by the threat of a very unpleasant physical reaction if they do consume alcohol. The severity of the disulfiram/ethanol reaction, or DER, depends on the amount of alcohol and disulfiram in the blood. The symptoms of the reaction include facial flushing, rapid heartbeat, palpitations, difficult breathing, lowered blood pressure, headaches, nausea, and vomiting.

A DER results when the drinker consumes alcohol, because disulfiram inhibits the functioning of an enzyme called aldehyde dehydrogenase. This enzyme is needed to convert acetaldehyde, which is produced when the body begins to oxidize the alcohol. Without the aldehyde dehydrogenase, the patient's blood level of acetaldehyde rises, causing the symptoms associated with DER.

Another alcohol-sensitizing agent is calcium carbimide, which is marketed under the brand name Temposil. Calcium carbimide produces physiological reactions with alcohol similar to those produced by disulfiram, but the onset of action is far more rapid, and the duration of action is much shorter.

ANTI-CRAVING MEDICATIONS. Another medication approved for the treatment of alcoholism is naltrexone, which appears to reduce the craving for alcohol. An injectable, long-acting form of naltrexone (Vivitrol) is also available.

Acamprosate is another anti-craving drug used to treat alcoholism in the United States. Acamprosate appears to reduce the frequency of drinking, but its effects on enhancing abstinence from alcohol are no greater than those of naltrexone. This drug does not appear to enhance the effectiveness of naltrexone if the drugs are given in combination.

Other medications are available to treat the symptoms of alcohol withdrawal, such as shakiness, nausea, and sweating that occur after someone with alcohol dependence stops drinking.

Alternative

Many clinical trials for the treatment or prevention of alcoholism are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2021, NIH reported 651 studies on alcohol use disorders.

QUESTIONS TO ASK YOUR DOCTOR

- Can alcoholism be treated without medications?
- How can I best understand the factors that led to my alcoholism?
- Can I recover?
- Are lifestyle changes required?
- Are there associated conditions that also require treatment?

A few examples include:

- The role of neuroactive steroids in stress, alcohol craving, and alcohol use in alcohol use disorders. (NCT03872128)
- Selective attention in alcohol use disorder. (NCT03816527)
- Pregabalin trial for the treatment of alcohol use disorder. (NCT04322305)
- The effect of rTMS to the prefrontal cortex in alcohol use disorder. (NCT03809286)

Clinical trial information is constantly updated by NIH, and the most recent information on alcoholism trials can be found at: <http://clinicaltrials.gov/ct2/results?term=alcoholism>.

Prognosis

The prognosis for recovery from alcoholism varies widely. The usual course of the disorder is one of episodes of intoxication beginning in adolescence or young adulthood, with full-blown dependence by the mid-20s to mid-30s. The most common pattern is one of periodic attempts at abstinence, alternating with relapses into uncontrolled drinking. On the other hand, it is thought that as many as 20% of persons diagnosed as alcohol-dependent achieve long-term sobriety even without medical treatment. It is difficult to compare the outcomes of the various treatment approaches to alcoholism, in part because their definitions of “success” vary. Some researchers count only total abstinence from alcohol as a successful outcome, while others regard curtailed drinking and better social adjustment as indicators of success. The role of genetic factors in the prognosis is still disputed. Available evidence suggests that such factors as the presence of a supportive partner or close friend in the alcoholic's life, or religious commitment, can outweigh genetic vulnerability to the disorder.

Alexander disease

Definition

Alexander disease is a rare genetic disease that may strike infants, children, or adults. Individuals with this disorder have abnormal nerve cells, specifically those known as glial cells. Depending on the severity of the disorder, individuals may experience progressive intellectual disability, seizures, and speech problems, among other symptoms. Additionally, they may have only very mild symptoms or none at all. Alexander disease is usually fatal.

Alternate names associated with the disease include dysmyelogenic leukodystrophy, dysmyelogenic leukodystrophy-megalobare, or dysmyelogenic leukodystrophy with megalobarencephaly; fibrinoid degeneration of astrocytes or fibrinoid leukodystrophy; hyaline panneuropathy, megalencephaly with hyaline inclusion, or megalencephaly with hyaline panneuropathy; or leukodystrophy with Rosenthal fibers.

Description

Alexander disease results from a genetic defect that affects the nervous system. This defect usually develops as a new mutation in the GFAP (glial fibrillary acidic protein) gene. Although in rare cases, individuals can inherit it when one of their parents also has the disease. Mutations affect the GFAP gene that carries the blueprint for making glial fibrillary acidic protein. This protein provides support and strength to certain cells, known as astroglial cells or astrocytes, that are important to the brain and the spinal cord.

The full range of astrocyte function is unknown, but in general, they form a structural and functional interface between nerve cells and other cells so that these cells can communicate. They also monitor the spinal cord and brain for damage due to injury or illness. Astrocytes may also participate in the function of cells, known as oligodendrocytes, which play a role in making and

Symptoms of Alexander disease

In infants	In children	In adults
Speech problems Feeding difficulties Delayed development Difficulty walking Progressively increasing muscle spasms Enlarged brain (megalencephaly) Water on the brain, often accompanied by an enlarged head Seizures, sometimes severe Mental retardation that becomes severe over time	Speech problems Feeding difficulties often due to problems swallowing Impaired coordination Difficulty walking Muscle spasms, particularly affecting the legs Weakness Inability to cough Abnormal curvature of the spine (kyphoscoliosis) Declining mental abilities, in some cases	Speech problems Difficulty swallowing Impaired coordination Sleep problems

Symptoms of Alexander disease (Gale)

maintaining the protein myelin. Myelin covers, protects, and insulates nerve fibers. In addition, astrocytes may also help to maintain the blood-brain barrier, a mechanism that acts as a sentry for the brain and only allows certain substances in the circulating blood to pass into the brain.

When individuals have the genetic mutation in the *GFAP* gene associated with Alexander disease, glial fibrillary acidic protein does not work as it should. This can, in turn, have an impact on astrocyte function, which can then affect myelin. Without enough properly working myelin, problems in the nervous system develop, and numerous symptoms can result.

Different types of Alexander disease exist and are based on the age of symptom onset. They are:

- Neonatal Alexander disease affects newborns and is characterized by seizures, hydrocephalus (water on the brain), and severe motor and intellectual disability. Death usually occurs within two years.
- Infantile Alexander disease is characterized by symptoms that appear in the first two years of life. It is the most common form of this disease. Initial symptoms include a progressive loss of developmental milestones, enlarged head with a large forehead, seizures and other neurological signs. The survival of children with this form of Alexander disease ranges from weeks to several years of age.
- Juvenile Alexander disease presents the first symptoms between the ages of 4 and 10 years with the average age of onset at 9.5 years. Symptoms can include ataxia, a gradual loss of intellectual function, seizures and occasionally, but not always, an enlarged head. The survival of individuals with this form of Alexander disease generally ranges from the teens to the twenty and thirties.
- Adult-onset Alexander disease has symptoms that may emerge in the late teens or later, but sometimes not

appearing until the person reaches an advanced age. The symptoms of the adult form are the most variable, and there have been some individuals described that are asymptomatic despite having characteristic findings on MRI or by DNA testing.

Genetic profile

Alexander disease is a rare condition that is caused by a mutation (pathogenic variant) in a gene, specifically the *GFAP* gene. It can be passed down from parent to child in autosomal dominant manner, which means that individuals can inherit it if one of their parents has the mutated gene. In most cases, however, the mutation (pathogenic variant) is a new one that develops in affected individuals and is not inherited from a parent. Symptoms range from mild (sometimes unnoticeable) to severe.

Located on chromosome 17, the *GFAP* gene carries the blueprint for making glial fibrillary acidic protein. Scientists have identified several dozen mutations (pathogenic variants) of this gene that lead to Alexander disease. The mutations often result from the addition or the deletion of some of the protein's normal complement of amino acids (the building blocks of proteins). When too many or too few amino acids are present, the protein's structure changes. Frequently in individuals with Alexander disease, the following sequence occurs:

- Altered glial fibrillary acidic protein builds up in the astrocytes.
- The accumulation of glial fibrillary acidic protein causes unusual fibers to form. These fibers are known as Rosenthal fibers and are not believed to occur in healthy individuals.
- Rosenthal fibers hinder the function of the astrocytes.
- The impaired astrocytes cause poor maintenance of myelin.

- The myelin deficiency is the root of Alexander disease symptoms.

Because Alexander disease can be an autosomal dominant disorder, adults with the mutated gene has a 50% chance of passing it to each child they may have. As noted, however, affected individuals usually develop new mutations in the gene. Therefore, most individuals who develop the disease have no family history of it.

Demographics

Alexander disease does not appear to occur more frequently in any ethnic group. In 2015, approximately 550 individuals had been diagnosed with this disease, but its overall prevalence is unknown.

Signs and symptoms

Individuals with Alexander disease may experience their first symptoms as infants, juveniles, or adults. Symptoms for the infantile form of the disease often include at least several of the following:

- Intellectual disability that becomes severe over time
- Progressively worse muscle spasms that often involve legs and arms (spastic quadriparesis)
- Feeding difficulties
- Delayed development
- Seizures, sometimes severe
- Enlarged brain (megalocephaly)
- Hydrocephalus or water on the brain, often accompanied by an enlarged head
- Speech problems
- Difficulty in walking, sometimes unable to walk

Symptoms for the juvenile form of the disease include the following:

- Speech problems
- Feeding difficulties often due to problems swallowing
- Weakness
- Inability to cough
- Difficulty in walking
- Impaired coordination
- Muscle spasms, particularly affecting the legs
- Abnormal curvature of the spine (kyphoscoliosis)
- Declining mental abilities in some cases

Symptoms for the adult-onset form of the disease may be much like those for the juvenile form, although they are typically milder and sometimes nonexistent. Generally, however, symptoms include the following:

- Speech problems

KEY TERMS

Astrocytes—Glial cells that occur in the brain and spinal cord.

Blood-brain barrier—A mechanism that acts as a sentry for the brain and only allows certain substances in the circulating blood to pass into the brain.

Glial cells—Supportive cells for nerve cells in the brain and spinal cord.

Hydrocephalus—Also known as “water on the brain,” the abnormal accumulation of cerebrospinal fluid in brain cavities.

Kyphoscoliosis—Abnormal curvature of the spine.

Megalocephaly—Enlarged brain.

Myelin—A fatty substance that covers, protects, and insulates nerve fibers.

Oligodendrocyte—A cell in the central nervous system that insulates the parts of nerve cells called axons.

Rosenthal fibers—Abnormal and irregularly shaped structures that form in astrocytes.

Spastic quadriparesis—Muscle spasms involve both the legs and the arms.

- Difficulty swallowing
- Impaired coordination
- Sleep problems

Diagnosis

Diagnosis is based on the constellation of symptoms in the affected individual. MRI findings and molecular genetic testing of the *GFAP* gene are used to confirm the diagnosis. MRI has proven to be a useful tool for diagnosing AD. The results often show high signal intensity of white matter in the frontal area and basal ganglia.

DNA sequencing of the *GFAP* gene is the most productive form of DNA testing for GFAP mutations and detects greater than 98% of mutations (pathogenic variants) in the *GFAP* gene. DNA sequencing is the molecular determination of the precise sequence of nucleotides in a sample of DNA. By looking at the coding regions (exons) of the *GFAP* gene and the junctions between these coding regions, mutations or changes in the sequence of nucleotides can be found. If no mutations are detected by sequencing the *GFAP* gene, then deletion/duplication testing which looks for copy number

QUESTIONS TO ASK YOUR DOCTOR

- Given that my child has been diagnosed with Alexander disease, is it possible that I, too, have the disease?
- Is there anything I can do to slow the decline in mental abilities in my child?
- I have been diagnosed with adult-onset Alexander disease. Based on the symptoms I have had, what can I expect in the coming years?
- Are any experimental treatments being researched to help promote myelin formation?

variants is performed. As of 2015, no deletions or duplications had been found in the *GFAP* gene.

If DNA sequencing does not detect a mutation (pathogenic variant) in a person who clinically appears to have Alexander disease, then other DNA testing techniques may be used. Multigene panels testing identifies groups of genes, *GFAP* gene and other genes, that cause diseases that have symptoms similar to Alexander disease.

Genomic testing with whole exome sequencing (WES) and whole genome sequencing (WGS) may also be performed. WES and WGS are performed by sequencing an entire genome, which is an individual's complete set of DNA, composed of approximately 22,000 genes. Whole exome sequencing is the sequencing of all of the coding portions of an individual's genome (known as the exome). Whole genome sequencing (WGS) is the sequencing of an individual's entire genome in both coding and non-coding regions. Both techniques are expensive and results can be difficult to interpret.

Procedures

The doctor may order an MRI (magnetic resonance imaging) or CT (computed tomography) scan to look for myelin, brainstem, or other abnormalities.

Treatment and management

No cure exists for Alexander disease, although doctors may be able to treat some of the symptoms.

Traditional

Treatments are available for some of the symptoms of this disease. For instance, individuals with feeding problems may require a nasogastric tube (feeding tube) in order to get the nutrition they need. For patients with

hydrocephalus, the doctor may recommend surgery to alleviate the fluid accumulation on the brain. Anti-epileptic drugs may be necessary to control seizure activity. Antibiotics are used to treat co-existing infections.

Individuals with Alexander disease should be assessed for learning disabilities and cognitive issues. Physical and occupational therapy may also be of value depending on their symptoms. In addition, they should have regular visits with a multidisciplinary team to assess and monitor symptoms development.

Drugs

The doctor may prescribe certain drugs to treat specific symptoms of this disease. These will vary from one patient to another.

Prognosis

Regardless of the form of the disease, symptoms typically progressively worsen as time goes by. In the infantile forms particularly, disease progression may be rapid, and affected individuals may die within a few years of the onset of the first symptoms.

The juvenile form of the disease usually progresses more slowly than the infantile form. While some patients with juvenile Alexander disease live into adulthood, many die young, often between 15 months and 12 years of the onset of symptoms.

Symptoms of the adult-onset form of the disease are generally milder than other forms of the disease, although this is not always the case. In some instances, the symptoms may be so mild as to be unnoticeable.

Prevention

There is no way to prevent Alexander disease.

Adults who have the disease should consider undergoing genetic counseling before deciding to have a child so that they fully understand the risks. Similarly, siblings of an individual with Alexander disease may want to consult a genetic counselor for family planning purposes. Pre-conception, prenatal, or preimplantation genetic diagnosis may be helpful in certain cases.

Alkaptonuria

Definition

Alkaptonuria is a rare, inherited disorder characterized by urine that turns dark when exposed to air, dark pigmentation of the cartilage and other tissues, and arthritis.

Description

Alkaptonuria (AKU) (sometimes spelled alcaptonuria) is a disorder in which a substance called homogentisic acid (HGA) accumulates in cells and connective tissues throughout the body. Large amounts of HGA also are excreted in the urine. In a process known as ochronosis, deposits of HGA form dark pigments in the skin, joints, and other tissues of the body. Over the long term, ochronosis leads to ochronotic arthritis, which is a painful inflammation and stiffening of the joints. AKU is also known as homogentisic acid oxidase deficiency, ochronosis, alkaptonuria ochronosis, or ochronotic arthritis.

History

The black urine that characterizes AKU has been recognized throughout history. It sometimes was considered to be a bad omen. The dark pigmentation of ochronosis has been identified in an Egyptian mummy from 1500 BCE.

AKU was one of the first inherited disorders to be identified as a deficiency in a single enzyme in one pathway of the body's metabolism. In 1902, Sir Archibald Garrod, after consultation with the famous geneticist William Bateson, proposed that the inheritance of AKU could best be described by Gregor Mendel's theory of the inheritance of recessive characteristics. These are inherited traits expressed in some of the offspring of parents who both carry the trait. The parents may or may not express the trait. In 1908, Garrod coined the term "inborn error of metabolism" to describe AKU and three other metabolic disorders. Furthermore, he suggested that AKU was due to a deficiency in a specific enzyme, a protein that catalyzes one step of a metabolic pathway.

Homogentisic acid

During normal metabolism, the 20 common amino acids, that are the building blocks of enzymes and other proteins, are broken down into simpler substances. This process provides energy for the body. The amino acids phenylalanine and tyrosine are converted to simpler substances in a series of eight steps. Each step in this pathway occurs through the action of a different enzyme. The first step in the pathway converts phenylalanine to tyrosine. The inherited disorder known as phenylketonuria results from a deficiency in the enzyme that carries out this first step.

AKU results from a deficiency in an enzyme called homogentisate 1,2-dioxygenase (HGD). This enzyme also is called homogentisic acid oxidase. It is responsible for the fourth step in the breakdown of phenylalanine and tyrosine, the conversion of HGA to 4-maleylacetoacetic acid. When there is a deficiency in active HGD, as in AKU, HGA cannot be broken down further. It accumulates in cells and tissues throughout the body, and large amounts of HGA are excreted in the urine.

Oxygen causes HGA molecules to combine with each other to form a very large molecule called a polymer. This polymer is a dark pigment similar to melanin, the pigment responsible for skin color. This pigment is formed in the tissues of the body, as well as in urine exposed to the oxygen in air. Oxygen can also convert HGA into a toxic substance called benzoquinone acetic acid.

HGA is excreted very quickly. In general, levels of HGA are kept quite low in individuals with AKU.

Alkaptonuria

Autosomal Recessive

1. High carrier frequency in Czechoslovakia

2. Low carrier frequency in other countries

Alkaptonuria: pedigree analysis chart (Gale)

Nevertheless, over time, large quantities of HGA, either as individual molecules or as a polymer, are deposited in the cartilage (the flexible tissue of the joints and other bony structures) and in other connective tissues of the body.

Granules of HGA pigment collect around collagen. This is the protein that makes up the fibers of connective tissues. Collagen is the most abundant protein in the body. It is a major structural component of cartilage, bone, tendons, ligaments, and blood vessels. Collagen also forms an important structural layer beneath the skin, and it holds together the cells of various tissues. The accumulation of HGA in connective tissues interferes with the body's ability to make new collagen. As a result, collagen fibers throughout the body are weakened. In particular, HGA weakens the collagen fibers in the cartilage of the joints.

Ochronosis

Initially, an ochre or yellowish-colored HGA pigment is deposited in the tissues of individuals with AKU. Over a period of years, the cartilage, bones, and skin begin to turn

a slate-blue or blue-black color. This pigmentation, or ochronosis, of the tissues eventually leads to a serious form of arthritis. Furthermore, as the HGA polymer accumulates, inflammation occurs. This causes calcium to be deposited in the joints in a process called calcification.

Genetic profile

AKU is an autosomal recessive disorder. It is autosomal because the gene encoding the HGD enzyme is located on chromosome 3, rather than on either of the X or Y sex chromosomes. AKU is a recessive trait because it only occurs when an individual has two copies of the defective gene, one inherited from each parent. The two defective HGD genes do not need to carry the same mutations. If the two mutations are identical, the individual is a homozygote. If the two mutations are different, the affected individual is called a compound heterozygote.

In individuals with a single defective *HGD* gene, at least 50% of the HGD enzyme has normal activity. These individuals have no symptoms of AKU. However, they are carriers of AKU and can pass the gene on to their offspring.

All of the offspring of two parents with AKU will inherit the disorder. All of the offspring of one parent with AKU and one parent with a single defective *HGD* gene will inherit at least one defective *HGD* gene. These offspring have a 50% chance of inheriting two defective genes and developing AKU. The offspring of one parent with AKU and one parent with normal *HGD* genes will inherit a defective gene from the affected parent, but will not develop AKU. The offspring of parents who both carry one defective *HGD* gene have a 50% chance of inheriting one defective *HGD* gene. They have an additional 25% chance of inheriting two such genes and developing AKU. Finally, the children of one parent with a single defective *HGD* gene and one parent with normal *HGD* genes have a 50% chance of inheriting the defective gene, but will not develop AKU.

A large number of different mutations have been identified in the *HGD* gene. These changes reduce or destroy the activity of the HGD enzyme. Mutational hot spots have also been identified in the gene. These are regions of the gene in which mutations are particularly likely to occur.

Demographics

As a recessive disorder, AKU requires two copies of the defective gene, one inherited from each parent. Thus, AKU is much more common in the offspring of couples who are related to each other, such as first or second cousins. As an autosomal disorder, AKU occurs equally among males and females. However, in general, the symptoms of arthritis appear at an earlier age in males and tend to be more severe than in females. The reason for this difference is not known.

AKU occurs with equal frequency among various races; however, the frequency varies substantially among different populations. It is most common in geographically isolated populations. The worldwide prevalence of AKU is estimated at between 1 in 100,000 and 1 in 250,000 individuals. However, some estimates are as low as 1 in 1,000,000 individuals and, in the United States, AKU frequency is estimated to be only 1 in 4,000,000.

AKU occurs with particularly high frequency in the Dominican Republic, Slovakia, and the Czech Republic. The frequency has been reported to be as high as 1 in 19,000 live births in Slovakia. The frequency of AKU is particularly low in Finland. Certain mutations occur only in *HGD* genes from Slovakia. Two specific mutations occur in 50% of all Slovaks with AKU. Other mutations in *HGD* appear to be unique to the Finnish population.

Signs and symptoms

Early symptoms

Often, the first sign of AKU is the dark staining of an infant's diapers from the HGA in the urine. However, a significant number of AKU-affected individuals do not have blackened urine, particularly if their urine is acidic. Other than darkened urine, AKU generally has no symptoms throughout childhood and early adulthood. Nevertheless, pigment is being deposited in the tissues throughout the early years. Occasionally, black ear wax and pigmentation under the arms may develop before the age of ten.

Ochronosis

Ochronosis, the pigmentation of the cartilage, usually does not become apparent until the fourth decade of life. Small rings or patches of slate-blue, gray, or black discoloration of the white, outer membranes of the eyeballs are one of the first visible symptoms. This usually begins when affected individuals are in their 30s. Thickening and discoloration of the cartilage of the ear usually begins in the following decade. This is indicative of the widespread staining of cartilage and other tissues. The ear cartilage may become stiff, irregularly shaped, and calcified (hardened with deposits of calcium).

Discoloration of the skin is due to the depositing of ochronotic pigment granules in the inner layer of the skin and around the sweat glands. The outer ear and nose may darken with a bluish tint. Pigmentation also may be visible on the eyelids, forehead, and armpits. Where the skin is exposed to the sun, and in the regions of the sweat glands, the skin may become speckled with blue-black discoloration. Sweat may stain clothes brown. Fingernails may become bluish.

The ochronotic effects of AKU on the cartilage and tendons are most visible on parts of the body where the connective tissues are closest to the skin. Pigmentation may be visible in the genital regions, the larynx (voice box), and the middle ear. Dark-stained tendons can be seen when the hand is made into a fist.

Arthritis

The symptoms of ochronotic arthritis are similar to those of other types of arthritis. However, the large, weight-bearing joints usually are the most affected in ochronotic arthritis. These include the joints of the hips, knees, and shoulders, and between the vertebrae of the spine. The joints become stiff and difficult to move. This arthritis develops at an unusually early age. In unaffected individuals, similar arthritis usually does not develop before age 55. Men with AKU develop arthritis in their

30s and 40s. Women with AKU usually develop arthritis in their 50s.

AKU can lead to osteoarthritis, a degenerative joint disease, and ochronotic arthropathy, which is characterized by the swelling and enlargement of the bones. Ankylosis, the adhesion of bones in the joints, also may occur. The pigment deposits may cause the cartilage to become brittle and susceptible to fragmenting. Individuals with AKU may be at risk for bone fractures.

Calcium deposits can lead to painful attacks similar to those of gout. This calcification may occur in the ear cartilage and in the lumbar disks of the lower back. The disks between vertebrae may become narrowed and eventually may collapse.

Organ damage

The coronary artery of the heart can become diseased as a result of AKU. The aortic valve of the heart may harden and narrow from calcification. Similar problems may develop with the mitral or left atrioventricular valve of the heart (mitral valvulitis). Deposits of pigment can lead to the formation of hard spots of cholesterol and fat (atherosclerotic plaques) in the arteries. This can put a person at risk for a heart attack.

Complications from the deficiency of the HGD enzyme arise primarily in the kidneys and the liver. HGD normally is most active in the kidneys, liver, small intestine, colon, and prostate. The calcification of the genital and urinary tract may lead to blockages in as many as 60% of individuals with ochronosis. Kidney stones and other kidney diseases may develop. Stones in the urine may occur in middle to late adulthood. Increasingly though, this condition is seen in children with AKU under the age of 15 and even as young as two. In men, pigment deposits may lead to stones in the prostate.

The teeth, the brain and spinal cord, and the endocrine system that produces hormones also may be affected by ochronosis. Breathing may become restricted due to the effects of ochronosis on the joints where the ribs attach to the spine. Deposits of pigment on the ear bones and on the membrane of the inner ear may lead to tinnitus, or ringing of the ears, and hearing problems.

Diagnosis

Visual diagnosis

AKU is often detected in early childhood because of the characteristic dark-staining of the urine. In adults, diagnosis usually is made on the basis of joint pain and skin discoloration. Most individuals with AKU

KEY TERMS

Alkaline—Having a basic pH; not acidic.

Amino acid—Organic compounds that form the building blocks of protein. There are 20 types of amino acids (eight are “essential amino acids” which the body cannot make and must therefore be obtained from food).

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Benzoquinone acetic acid—Toxic compound that is formed when oxygen reacts with homogentisic acid.

Calcification—A process in which tissue becomes hardened due to calcium deposits.

Collagen—The main supportive protein of cartilage, connective tissue, tendon, skin, and bone.

Compound heterozygote—Having two different mutated versions of a gene.

Homogentisate 1,2-dioxygenase (HGD)—Homogentisic acid oxidase, the fourth enzyme in the metabolic pathway for the breakdown of phenylalanine.

Homogentisic acid (HGA)—2,5-Dihydroxyphenylacetic acid, the third intermediate in the metabolic pathway for the breakdown of phenylalanine.

Homozygote—Having two identical copies of a gene or chromosome.

Melanin—Pigments normally produced by the body that give color to the skin and hair.

Mendel, Gregor—Austrian monk who discovered the basic principles of heredity.

Ochronosis—A condition marked by pigment deposits in cartilage, ligaments, and tendons.

Phenylalanine—An essential amino acid that must be obtained from food since the human body cannot manufacture it.

Polymer—A very large molecule, formed from many smaller, identical molecules.

Tyrosine—An aromatic amino acid that is made from phenylalanine.

have pigment visible in the whites of their eyes by their early 40s.

A family history of AKU helps with the diagnosis. Since many individuals with AKU have no symptoms, siblings of affected individuals should be tested for the disorder.

Identification of HGA

An individual with AKU may excrete as much as 4–8 g of HGA per day in the urine. There are several simple methods to test for HGA in the urine: the addition of sodium hydroxide (an alkali) to the urine will turn it dark; urine with HGA turns black when reacted with iron chloride; and alkaline urine containing HGA blackens photographic paper. In the laboratory, HGA can be identified in the urine using a technique called gas chromatography-mass spectroscopy. This technique separates and identifies the components of a mixture.

There are a number of methods for identifying HGA in the blood and tissues. These include procedures for separating HGA from other components of the blood and instruments that can detect the characteristic color of HGA. With AKU, the concentration of HGA in the blood is approximately 40 micromolar, or 40 micromoles of per liter.

Microscopic examination

With AKU, there usually is visible black staining of cartilage in various body regions, particularly the larynx, trachea (windpipe), and cartilage junctions. Heavy deposits of pigment also occur in the bronchi (the air passages to the lungs). Pigment on the inside and outside of the cells of these tissues can be seen with a microscope.

A skin biopsy, the removal of a small piece of skin, may be used to obtain tissue for examination. The tissue is stained with dyes to reveal the yellowish-brown pigment deposits on the outside of skin cells. Pigment deposits also occur in cells of the endothelium (the thin layer of cells that line blood vessels and other tissues), in the sweat glands, and in the membranes below the skin. These pigments will not fade, even after three days in a solution of bleach.

Skeletal x-rays

X-ray examination is used to detect calcification of the joints. Since many individuals with AKU do not have dark-staining urine, x-ray evidence of osteoarthritis may indicate a need to test for the presence of HGA in the urine. However, osteoarthritis usually affects the smaller joints; whereas ochronosis most often affects the large joints of the hips and shoulders. Spinal x-rays may show dense calcification, degeneration, and fusion of the disks of the vertebrae, particularly in the lumbar region of the lower back. Chest x-rays are used to assess damage to the valves of the heart.

Other procedures

Physicians may order computerized tomography (CT) scans of the brain and chest or magnetic resonance

imaging (MRI) of affected joints. An electrocardiogram (ECG or EKG) may reveal signs of heart complications resulting from AKU. Kidney problems may be diagnosed by ultrasound, the use of sound waves to obtain images of an organ. Lung function tests and hearing tests may be performed to assess additional complications.

Acquired ochronosis

In addition to being a complication of AKU, ochronosis can be acquired. In the past, ochronosis developed from the repeated use of carbolic acid dressings for treating chronic skin ulcers. The prolonged use of the drug quinacrine (atabrine) can cause ochronosis, with pigmentation occurring in many of the same sites as with AKU. Ochronosis can also result from the use of bleaching creams containing hydroquinone. Certain other substances, including phenol, trinitrophenol, quinines, and benzene, can cause ochronosis. However, these forms of ochronosis do not lead to joint disease and, unlike ochronosis from AKU, are reversible.

Treatment and management

The binding of HGA to collagen fibers is irreversible. Treatment of AKU is directed at reducing the deposition of pigment and thereby minimizing arthritis and heart problems in later life.

Vitamin C

Often, high doses (about 1 gm per day) of ascorbic acid (vitamin C) are administered to older children and adults with AKU. Ascorbic acid appears to slow the formation of the HGA polymer and decrease the binding of the polymer to connective tissues. Vitamin C reduces the amount of toxic benzoquinone acetic acid in the urine. However, the amount of HGA in the urine does not decrease. Furthermore, vitamin C does not appear to interrupt the progress of the disease.

Dietary restrictions

Sometimes individuals with AKU are placed on low-protein diets. This limits the intake of phenylalanine and tyrosine from proteins. If the body has lower amounts of phenylalanine and tyrosine to break down, less HGA will be formed. However, both of these amino acids are necessary for making proteins in the body. Furthermore, phenylalanine is an essential amino acid that must be obtained from food, since the human body cannot produce it. Adult males require approximately 2 gm per day of phenylalanine. Phenylalanine also is present in some artificial sweeteners.

Restricting protein intake to no more than the daily protein requirement may be beneficial for children with

QUESTIONS TO ASK YOUR DOCTOR

- What are possible side effects of long-term vitamin C therapy?
- Can you provide a low protein diet regime?
- How do the benefits of long-term use of painkillers compare with the risks?
- What is the expected outcome of joint replacement surgery?

AKU. Such diets appear to substantially reduce the amount of benzoquinone acetic acid in the urine. In children under the age of 12, low-protein diets significantly reduce the amount of HGA in the urine, as well. However, these diets seem to have little effect on older children and young adults with AKU, and low-protein diets are difficult to maintain. When low-protein diets are prescribed, the levels of amino acids in the blood must be monitored, to assure that there is no deficiency in phenylalanine.

Ochronosis

Most treatment of AKU is directed at the diseased joints. The treatment for ochronosis is the same as for other forms of degenerative arthritis. Treatments include painkillers, physical therapy, rehabilitation, orthopedic supports, and rest. Chiropractic manipulations and exercise regimens also are utilized.

Treatment of ochronotic arthritis eventually may require hip and/or knee joint replacements with artificial materials. In older individuals, fusion of the lumbar discs of the lower spine may be necessary. Aortic valve replacement may be necessary to treat heart disease.

Future drug treatment

The National Institutes of Health are undertaking clinical research studies to better understand the clinical, biochemical, and molecular aspects of AKU. These studies are in preparation for clinical trials of a new drug, nitisinone, to treat AKU. A 2005 study showed that nitisinone was effective in reducing HGA levels in individuals with AKU. Other studies are being conducted.

Prognosis

There is no cure for AKU. Essentially all individuals with AKU eventually experience arthritic symptoms, particularly arthritis of the hips, knees, and spine. The bone and joint disease may become debilitating by the sixth to eighth decades of life. Furthermore, cardiovascular

involvement and ochronotic skin abnormalities are to be expected with AKU.

Despite these difficulties, individuals with AKU have normal life expectancies. Although there is an increased risk of heart attack in later life, most individuals with AKU die of causes unrelated to the disorder.

Margaret Alic, PhD

Alpha thalassemia

Definition

Thalassemia describes a group of genetic blood disorders characterized by absent or reduced production of hemoglobin, the oxygen-carrying protein inside the red blood cells. There are two basic groups of thalassemia disorders: alpha thalassemias and beta thalassemias. These conditions cause varying degrees of anemia, which can range from mild to life-threatening.

Description

Normal adult hemoglobin consists of four protein chains: two alpha and two beta globins. Each chain

carries a group called a heme, a ring-like molecule that contains the iron that binds the oxygen. Thalassemias are classified according to the globin that is affected, hence the names *alpha* and *beta* thalassemia. Although both classes of thalassemia affect the same protein, the alpha and beta thalassemias are distinct diseases that affect the body in different ways.

Types of alpha thalassemia

People whose hemoglobin does not produce enough alpha globin have alpha thalassemia. The condition is the result of changes in the genes that code for making alpha chains in hemoglobin. There are four types of alpha thalassemia:

- Hemoglobin H disease (HbH): This thalassemia causes severe anemia and serious health problems such as an enlarged spleen, and bone deformities.
- Alpha thalassemia major: this is the most severe type of alpha thalassemia. It is also called hydrops fetalis or Hb Bart syndrome. Most individuals affected by this condition die before or shortly after birth.
- Alpha thalassemia minor: individuals affected by this thalassemia have smaller red blood cells known as microcytes, and display mild anemia. It is often misdiagnosed as iron deficiency anemia.
- Alpha thalassemia, silent carrier: this thalassemia is difficult to detect because it usually does not cause symptoms, hence its name.

Genetic profile

Humans normally make several types of hemoglobin. An individual's stage in development determines whether he or she makes primarily embryonic, fetal, or adult hemoglobins. Normal adult hemoglobin (HbA) is a tetrameric protein consisting of four chains: two alpha

globins and two beta globins, each chain also containing a heme molecule. It is the major hemoglobin component of red blood cells (95%). In addition, red blood cells contain other minor hemoglobin forms: hemoglobin A2 (HbA2) consisting of two alpha chains and two delta chains (~3%) and hemoglobin F (HbF), consisting of two alpha chains and two gamma chains (~2%). If a person cannot produce enough of either alpha or beta globins, the red blood cells do not form normally and cannot carry oxygen properly, resulting in anemia.

All thalassemias are caused by deletions or modifications in the genes that control globin production. These genes are located on chromosome 16 (alpha globin genes) and chromosome 11 (beta, gamma, and delta genes). Mutations modify the amount of alpha globin relative to that of the other globins being produced, leading to an abnormal hemoglobin ratio and decreased hemoglobin production. The globin that is produced in normal amounts over the other globin accumulates and forms aggregates that damage the red blood cell membrane.

The thalassemias are inherited in an autosomal recessive pattern, meaning that a genetic change must be inherited from both the mother and the father. The severity of the disease is influenced by the exact thalassemia mutations inherited, as well as other genetic and environmental factors. There are rare exceptions, notably with beta thalassemia, in which globin gene mutations exhibit a dominant pattern of inheritance in which only one gene needs to be altered in order to see disease expression.

Alpha thalassemia

In alpha thalassemia, beta globins are produced in excess over the alpha globins, which leads to the formation of beta globin tetramers that also accumulate and interfere with erythropoiesis. Most individuals have four normal copies of the alpha globin genes, two copies

Thalassemia: pedigree analysis chart (Gale)

on the short arm of chromosome 16. There are two alpha globin genes in humans, *HBA1* and *HBA2*, located in what is known as the alpha locus at chromosome 16p13.3.

These genes make the alpha globin component of HbA. Alpha globin is also a component of HbF and HbA2. Defects in the alpha globin genes are usually deletions of the genes rather than mutations, resulting in the absence of alpha globin. The signs and symptoms of alpha thalassemia tend to be more severe when the disease results from mutations in the alpha-globin genes than when it is caused by deletions of these genes. Because there are four genes (instead of the usual two) to consider when looking at alpha globin gene inheritance, there are several alpha globin types that are possible.

Absence of one alpha globin gene leads to a condition known as silent alpha thalassemia trait or alpha thalassemia minima. This condition causes no health problems and can be detected only by special genetic testing. Alpha thalassemia trait, also known as alpha thalassemia minor, occurs when two alpha globin genes are missing. This condition can occur in two ways. The genes may be deleted from the same chromosome, causing the ‘cis’ type of alpha thalassemia trait. Alternately, they may be deleted from different chromosomes, causing the ‘trans’ type of alpha thalassemia trait. In both instances, there are no associated health problems, although the trait status may be detected by more routine blood screening.

Hemoglobin H (HbH) disease results from the deletion of three alpha globin genes, such that there is only one functioning gene. Typically, this condition can occur when one parent carries the silent alpha thalassemia trait and the other parent carries the ‘cis’ type of the alpha thalassemia trait. In this situation, there is a 25% chance for hemoglobin H disease in each of such a couple’s children.

Hemoglobin H disease-like symptoms can also be a part of a unique condition called alpha thalassemia intellectual disability syndrome 16 (ATR-16). Alpha thalassemia intellectual disability syndrome results from the deletion of a significant amount of chromosome 16, affecting the alpha globin genes. This condition is usually not inherited but occurs sporadically in affected individuals. Affected individuals have mild hemoglobin H disease, mild-to-moderate intellectual disability, and characteristic facial features. This syndrome can also occur as a sex-linked form (ATR-X) in which a mutation is inherited in a particular gene on the X chromosome; it affects only males. The ATR-X syndrome is more common than the ATR-16 syndrome. This gene influences alpha globin production, as well as various other developmental processes. Individuals affected with this form of the syndrome tend to have more severe intellectual

Illustration of normal and malformed blood cells affected by alpha thalassemia. (joshya/Shutterstock)

disability, delayed development, nearly absent speech, characteristic facial features, and genitourinary abnormalities.

Alpha thalassemia major results from the deletion of all four alpha globin genes, such that there are no functioning alpha globin genes. This condition can occur when both parents carry the ‘cis’ type of the alpha thalassemia trait. In this situation, there is a 25% chance for alpha thalassemia major in each of a couple’s children.

Demographics

The thalassemias are among the most common single-gene diseases worldwide, with more than 100,000 babies worldwide born each year with severe forms of thalassemia, resulting in some 15 million people having thalassemic disorders. It is estimated that there are 270 million carriers of mutant globin genes that can potentially cause severe forms of thalassemia. Both alpha and beta thalassemia have been described in individuals of almost every ancestry, but the

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Bilirubin—A yellow pigment that is the end result of hemoglobin breakdown. This pigment is metabolized in the liver and excreted from the body through the bile. Bloodstream levels are normally low; however, extensive red cell destruction leads to excessive bilirubin formation and jaundice.

Bone marrow—A spongy tissue located in the hollow centers of certain bones, such as the skull and hip bones. Bone marrow is the site of blood cell generation.

Bone marrow transplantation—A medical procedure used to treat some diseases that arise from defective blood cell formation in the bone marrow. Healthy bone marrow is extracted from a donor to replace the marrow in an ailing individual. Proteins on the surface of bone marrow cells must be identical or very closely matched between a donor and the recipient.

Desferoxamine—The oldest of three drugs used in iron chelation therapy. It aids in counteracting the

life-threatening buildup of iron in the body associated with long-term blood transfusions.

Ferritin—An intracellular protein that stores iron and releases it in a controlled manner. Ferritin in blood plasma is an indirect marker of the total amount of iron stored in the body.

Globins—A family of protein chains found in hemoglobin. Normal adult hemoglobin has two alpha globin chains and two beta globin chains.

Heme—The iron-containing molecule in hemoglobin that serves as the site for oxygen binding. Each of the four hemoglobin chains has one heme molecule.

Hemoglobin—Tetrameric protein in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells. Hemoglobin consists of four chains, each containing a heme molecule.

Hemoglobin A (HbA)—Normal adult hemoglobin; it consists of two alpha globins and two beta globins.

Hemoglobin electrophoresis—A laboratory test that separates molecules based on their size, shape, or electrical charge.

Hemoglobin F (HbF)—Fetal hemoglobin; it consists of two alpha and two gamma globins. HbF is

conditions are more common among certain ethnic groups. Unaffected carriers of all types of thalassemia traits do not experience health problems. In fact, the thalassemia trait protects against malaria, a disease caused by bloodborne parasites transmitted through mosquito bites. According to a widely accepted theory, most genetic mutations that cause thalassemia occurred multiple generations ago. Coincidentally, these mutations increased the likelihood that carriers would survive malaria infection. Survivors passed the mutation onto their offspring, and the trait became established throughout areas where malaria is common. As populations migrated, so did the thalassemia traits.

The frequency of hemoglobin H disease and alpha thalassemia major depends on the type of alpha thalassemia trait. The populations in which alpha thalassemia diseases are most common include Southeast Asians and Chinese (particularly Southern Chinese). Alpha thalassemia also occurs frequently in people from Mediterranean countries, North Africa, the Middle East, India, and Central Asia.

Determining prevalence figures for alpha thalassemia is even more difficult due to increased limitations in

diagnostic testing. All types of alpha thalassemia disease are most common among people of Southeast Asian and Chinese descent, for reasons that become clearer with an understanding of the underlying genetics of alpha thalassemia. For example, one study of 500 pregnant women in Northern Thailand estimated a frequency of one in 500 pregnancies affected by alpha thalassemia major.

The frequency of alpha thalassemia disease is significantly lower in the United States owing primarily to immigration patterns. The incidence of alpha thalassemia is low among Caucasians in the United States. However, it is estimated that about 15% of African Americans are silent carriers of alpha thalassemia and 3% have alpha thalassemia trait. However, at least one state, California, has observed growing hemoglobin H disease incidence rates that are high enough to justify universal newborn screening for the condition.

Signs and symptoms

Hemoglobin H disease

Absence of three alpha globin genes causes an imbalance of alpha and beta globin proteins in the red

produced by the fetus in utero and until about 48 weeks after birth. At this stage, the production of HbA rapidly increases while that of HbF drops off.

Hepatomegaly—An abnormally enlarged liver.

HLA type—The unique set of proteins called human leukocyte antigens. These proteins are present on each individual's cells. They allow the immune system to recognize 'self' from 'non-self'. HLA type is particularly important in organ and tissue transplantation.

Hydrops fetalis—A condition in which excess fluid builds up in a fetus's body prior to birth.

Hydroxyurea—A drug that has been shown to induce production of fetal hemoglobin. HbF has a pair of gamma-globin molecules instead of the beta-globins of HbA. Higher-than-normal levels of HbF can alleviate some of the symptoms of thalassemia.

Iron deficiency anemia—A decrease in the number of red cells in the blood caused by too little iron in the diet, poor absorption of iron by the body, or loss of blood.

Iron overload—A side effect of frequent blood transfusions in which the body accumulates

abnormally high levels of iron. Iron deposits can form in organs, particularly the heart, and cause life-threatening damage.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Microcyte—An abnormally small red blood cell.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Placenta—The organ responsible for oxygen and nutrition exchange between a pregnant mother and her developing baby.

Red blood cells (RBCs)—Hemoglobin-containing blood cells that transport oxygen from the lungs to tissues. In the tissues, the red blood cells exchange their oxygen for carbon dioxide, which is brought back to the lungs to be exhaled.

Screening—Process through which carriers of a trait may be identified within a population.

Splenomegaly—Enlargement of the spleen.

Tetramer—Protein that consists of four amino acid chains.

blood cells. The excess beta globin proteins tend to come together to form hemoglobin H, which is unable to release oxygen to the tissues. In addition, hemoglobin H tends to precipitate out in the cells, causing damage to the red blood cell membrane. When affected individuals are exposed to certain drugs and chemicals known to make the membrane more fragile, the cells are thought to become vulnerable to breakdown in large numbers, a complication called hemolytic anemia. Fever and infection are also considered to be triggers of hemolytic anemia in hemoglobin H disease. This process can result in fatigue, paleness, and a yellow discoloration of the skin and whites of eyes called jaundice. Other complications of HbH disease include ulcers on the legs, gallstones, short limbs, and compression fractures of the spine.

Usually, the anemia is mild enough not to require treatment. Severe anemia events may require blood transfusion, however, and are usually accompanied by such other symptoms as dark feces or urine and abdominal or back pain. These events are uncommon in hemoglobin H disease, although they occur more frequently in a more serious type of hemoglobin H disease called hemoglobin H/Constant Spring disease. Individuals affected with this

type of hemoglobin H disease are also more likely to have enlarged spleen and other spleen problems.

Alpha thalassemia major (Hb Bart syndrome)

Because alpha globin is a necessary component of all major hemoglobins and some minor hemoglobins, absence of all functioning alpha globin genes leads to serious medical consequences that begin even before birth. Affected fetuses develop severe anemia as early as the first trimester of pregnancy. The placenta, heart, liver, spleen, and adrenal glands may all become enlarged. Fluid can begin collecting throughout the body as early as the start of the second trimester, causing damage to developing tissues and organs. Growth retardation is also common. Affected fetuses usually miscarry or die shortly after birth. In addition, women carrying affected fetuses are at increased risk of developing complications of pregnancy and delivery. Up to 80% of such women develop toxemia, a disturbance of metabolism that can potentially lead to convulsions and coma. Other maternal complications include premature delivery and increased rates of cesarean section, as well as hemorrhage after delivery.

Diagnosis

Thalassemia may be suspected if an individual shows signs that are suggestive of the disease. In all cases, however, laboratory diagnosis is essential to confirm the exact diagnosis and to allow for the provision of accurate genetic counseling about recurrence risks and testing options for parents and affected individuals. Screening is likewise recommended to determine trait status for individuals of high-risk ethnic groups.

The following tests are used to screen for thalassemia disease and/or trait:

- Complete blood count
- Hemoglobin electrophoresis with quantitative hemoglobin A2 and hemoglobin F
- Free erythrocyte-protoporphyrin (or ferritin or other studies of serum iron levels)

A complete blood count will identify low levels of hemoglobin, microcytes (abnormally small red blood cells), and other red blood cell abnormalities that are characteristic of a thalassemia diagnosis. Since thalassemia trait can sometimes be difficult to distinguish from iron deficiency, tests to evaluate iron levels are important. A hemoglobin electrophoresis is a test that can help identify the types and quantities of hemoglobin made by an individual. This test uses an electric field applied across a slab of gel-like material. Hemoglobins migrate through this gel at various rates and to specific locations, depending on their size, shape, and electrical charge. Isoelectric focusing and high-performance liquid chromatography (HPLC) use similar processes to separate hemoglobins and can be used instead of hemoglobin electrophoresis to determine the types and quantities of hemoglobin present. Hemoglobin electrophoresis results are usually within the normal range for all types of alpha thalassemia. However, hemoglobin A2 levels and sometimes hemoglobin F levels are elevated when beta thalassemia disease or trait is present. Hemoglobin electrophoresis can also detect structurally abnormal hemoglobins that may be coinherited with a thalassemia trait to cause thalassemia disease (i.e., hemoglobin E) or other types of hemoglobin disease (i.e., sickle hemoglobin). Sometimes DNA testing is needed in addition to the screening tests. This test can be performed to help confirm the diagnosis and establish the exact genetic type of thalassemia.

Diagnosis of thalassemia can occur under various circumstances and at various ages. Several states offer thalassemia screening as part of the usual battery of blood tests done for newborns. This screening allows for early identification and treatment. Thalassemia can be identified before birth through the use of prenatal diagnosis. Chorionic villus sampling (CVS) can be offered as early

QUESTIONS TO ASK YOUR DOCTOR

- How can you determine whether the symptoms I notice in my child are those of thalassemia?
- What is the difference between alpha thalassemia and beta thalassemia?
- Can alpha thalassemia be treated, and, if so, what medications and procedures will my child need?
- What is the prognosis for my child if the condition is diagnosed as alpha thalassemia?

as 10 weeks of pregnancy and involves removing a sample of the placenta made by the baby and testing the cells. Amniocentesis is generally offered between 15 and 22 weeks of pregnancy, but can sometimes be offered earlier. Two to three tablespoons of the fluid surrounding the baby is removed. This fluid contains fetal cells that can be tested.

Pregnant women and couples may choose prenatal testing in order to prepare for the birth of a baby that may have thalassemia. Alternately, knowing the diagnosis during pregnancy allows for the option of pregnancy termination. Preimplantation genetic diagnosis (PGD) is a relatively new technique that involves in-vitro fertilization followed by genetic testing of one cell from each developing embryo. Only the embryos unaffected by thalassemia disease are transferred back into the uterus. PGD is currently available on a research basis only and is relatively expensive.

Imaging studies are not useful in diagnosing alpha thalassemia in adults but are often helpful in evaluating patients for such complications as splenomegaly, gallstones, or hepatomegaly. Ultrasound, however, can be used to evaluate the cardiovascular function and hemodynamic status of fetuses suspected of having alpha thalassemia major.

Treatment and management

Hemoglobin H disease

Hemoglobin H disease (HbH) is a relatively mild form of thalassemia that may go unrecognized. It is not generally considered a condition that will reduce one's life expectancy. Education is an important part of managing the health of an individual with hemoglobin H disease. It is important to be able to recognize the signs of severe anemia that require medical attention. It is also important to be aware of the medications, chemicals, and other

exposures to avoid due to the theoretical risk they pose of causing a severe anemia event.

When severe anemia occurs, it is treated with blood transfusion therapy. For individuals with hemoglobin H disease, this is rarely required. For those with the hemoglobin H/Constant Spring form of the disease, the need for transfusions may be intermittent or ongoing. A reasonable estimate would be on a monthly basis and requiring deferoxamine (Desferal) treatment, which is given intravenously. Deferasirox (Exjade), a newer chelating agent, is now preferred to deferoxamine because it is orally administered. Individuals with this more severe form of the disease may also have an increased chance of requiring a splenectomy (surgical removal of an enlarged and/or overactive spleen).

Pregnant women with HbH disease should be carefully monitored because they are at increased risk of severe anemia, preeclampsia, congestive heart failure, and miscarriage.

Alpha thalassemia major (Hb Bart syndrome)

Because alpha thalassemia major is most often a condition that is fatal in the prenatal or newborn period, treatment has previously been focused on identifying affected pregnancies in order to provide appropriate management to reduce potential maternal complications. Pregnancy termination provides one form of management. Increased prenatal surveillance and early treatment of maternal complications is an approach that is appropriate for mothers who wish to continue their pregnancy with the knowledge that the baby will most likely not survive.

In recent years, there have been a handful of infants with this condition who have survived long-term. Most of these infants received experimental treatment including transfusions before birth, early delivery, and even bone marrow transplantation before birth, although the latter procedure has not yet been successful. A still newer therapy is in utero hematopoietic stem cell transplantation (IUHCTx). For those infants that survive to delivery, there seems to be an increased risk of developmental problems and physical effects, particularly heart and genital malformations. Otherwise, their medical outlook is similar to a child with beta thalassemia major, with the important exception that ongoing lifelong blood transfusions begin right at birth.

Clinical trials

Clinical trials on alpha thalassemia are currently sponsored by the National Institutes of Health (NIH) and other agencies. Most are studies of hydroxyurea or chelating agents (currently approved or investigational).

However, some are longitudinal studies of patients with milder forms of alpha thalassemia. Clinical trial information is constantly updated by NIH and the most recent information on thalassemia trials can be found at: <http://clinicaltrials.gov/search/>

Prognosis

The prognosis for individuals who are silent alpha thalassemia carriers and those with alpha thalassemia trait is excellent. Persons with HbH disease, however, often have shortened lifespans although most survive into adulthood. Patients with HbH disease are at risk of severe anemia and have a lifelong requirement for transfusions.

The prognosis of patients with the most serious types of thalassemia has improved drastically in the last several years following recent medical advances in transfusion, chemotherapy, and transplantation therapy. Advances continue and promise to improve the life expectancy and quality of life further for affected individuals.

Alpha-1 antitrypsin deficiency

Definition

Alpha-1 antitrypsin deficiency (AATD) is one of the most common inherited diseases in Caucasians of European descent. AATD is caused by low amounts of, and abnormalities in, alpha-1 antitrypsin protein (AAT). People with AATD are more likely to have lung and liver problems. Lung problems are more common in people with AATD who are smokers.

Description

The alpha-1 antitrypsin protein (AAT) is a protease inhibitor, made mostly in the liver. It inactivates other proteins called proteases. This is an important function, as proteases themselves disable proteins. In the human body, the levels of proteases and their inhibitors need to be balanced so that proteases can perform their functions but not over-perform, which can lead to problems.

A protease called neutrophil elastase is the most important target of AAT. It protects the lungs against bacteria and other foreign particles. However, too much neutrophil elastase can destroy lung tissue. AAT ensures that there is not too much neutrophil elastase.

People with AATD have low amounts of, and abnormalities in, AAT, which means that they do not have enough AAT protein or that it does not work as well, resulting in increased amounts of proteases like Neutrophil elastase. This condition, in turn, can cause damage to the lung and liver and other less-common symptoms. Buildup of the abnormal AAT can also cause liver damage.

Genetic profile

The *SERPINA1* gene (serpin peptidase inhibitor, clade A [alpha-1 antiproteinase, antitrypsin] member 1), located on chromosome 14, is responsible for the production of AAT. Variations (mutations) in the *SERPINA1* gene can lead to lower amounts or abnormal alpha-1 antitrypsin protein (AAT) being produced by the body. To date, over 120 variations (mutations) of the *SERPINA1* gene that influence the AAT being produced have been identified.

AATD is inherited in an autosomal codominant pattern, which means two different versions (alleles) of the *SERPINA1* gene can be active in an individual with both versions (alleles) contributing to the amount and type of AAT being produced.

The most common allele of the *SERPINA1* gene is called M, and it produces a normal amount and type of AAT. Most people have two copies of the M allele (MM), and they produce normal amounts and a normal type of AAT. Other alleles of the *SERPINA1* gene produce reduced amounts and/or abnormal AAT and cause AATD. The most common of these alleles are the (Z) and (S) alleles. Individuals with two Z alleles usually have the most severe AATD. Even those who have one Z allele and one normal allele M (ZM) may have an increased risk of developing symptoms of AATD. People with SS have somewhat lower levels of AAT but don't typically have symptoms. Individuals with SZ, on the other hand, are at increased risk for symptoms but less so than those with ZZ. The F allele is rarer. Individuals with this allele have near-normal levels of AAT, but the protein doesn't work properly. People with the F allele seem to have an increased risk of lung problems but not liver problems. The I allele is also rare and similar to the S allele. More than 95% of all severely AAT-deficient individuals have either the ZZ or SZ genotype.

Demographics

AATD is most common in Caucasians, especially those of Northern European descent. It is less common in populations of Asian, African, and American Indian descent. Approximately one in 2,500 Caucasians has two Z genes. These individuals account for 1% of all emphysema patients. Because people with one *SERPINA1* Z allele and one other deleterious *SERPINA1* allele may also have symptoms, the number of people at risk to have AATD associated lung disease is greater than one in 2,500. Approximately one in 20 Caucasians has one Z allele and one normal M allele. The number of Caucasians with one S allele and one normal allele is even higher. Approximately one in 1,000 Caucasians of Northern European descent has two S alleles. The National

Institutes of Health estimate that 161 million people have an S or Z allele.

Signs and symptoms

The first symptoms in adults with AATD are often shortness of breath with mild activity and problems exercising caused by a lung disease called chronic obstructive pulmonary disease (COPD). Some people with AATD get an early-onset, rapidly progressive type of COPD, called emphysema. Emphysema is caused by damage to the lungs; it begins with breathlessness during exertion and progresses to shortness of breath at all times. People with AATD can also have frequent lung infections, tiredness, rapid heartbeat, vision problems, and weight loss. Adults with AATD are at increased risk for asthma, liver disease and liver cancer, and, more rarely, tender bumps under the skin called panniculitis. Some children with AATD have liver disease. The chance that someone will have symptoms, the age of onset, and the severity of symptoms depend on the alleles that they have and their environmental exposures.

Lung disease

Approximately 60% to 70% of the people with two Z alleles (ZZ) develop chronic lung disease. Shortness of breath with exertion may begin before age 40 and progress rapidly to incapacitating emphysema. Life expectancy may be reduced by 10 to 15 years and is reduced further for people with two Z alleles who smoke. Some individuals with two Z alleles never develop chronic lung disease, however. Individuals with MZ alleles and SZ alleles appear to be at slightly increased risk for lung problems. The chances appear to be less than for those with two major alleles (ZZ). The age of onset of symptoms and the severity seem to be less in MZ and ZS individuals.

Environmental exposures significantly affect whether a person will develop symptoms. Smoking puts individuals with AATD at much greater risk of developing emphysema. The Z allele protein functions 1,000 times less efficiently in smokers. People with AATD who are not exposed to harmful environmental factors are less likely to develop emphysema. If people with two Z alleles stop smoking before they develop lung disease, their life expectancy increases, and the risk of lung disease decreases. Respiratory infections can also cause a risk of lung damage, because they increase the level of harmful neutrophil elastase in the lungs. Infections should, therefore, be treated promptly.

Liver disease

The risks of liver disease and liver cancer are increased in individuals with AATD. The highest risk is

KEY TERMS

Alleles—Different versions or alternative forms of a gene. We inherit two alleles for most genes.

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Bronchiectasis—Permanent enlargement of parts of the airways of the lung.

Emphysema—A chronic lung disease that begins with breathlessness during exertion and progresses to shortness of breath at all times, caused by destructive changes in the lungs.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein. A gene is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Granulomatosis with Polyangitis—Permanent enlargement of parts of the airways of the lung.

Necrotizing Panniculitis—Raised bumps under the skin that develop into ulcers.

Proteins—Important building blocks of the body, composed of amino acids. Proteins are involved in the formation of bodily structures and the regulation of basic bodily functions.

for individuals with ZZ alleles. The liver disease appears to be caused by buildup of abnormal AAT in the liver. Infants and children with AATD may have abnormal liver function and inflammation. The abnormal liver function they develop is called cholestasis, a condition in which the liver stops secreting a digestive fluid called bile. A buildup of bile causes cholestatic jaundice (yellowing of the skin). These abnormalities sometimes progress to liver disease and liver failure, which is fatal without a liver transplant. In other children, liver function returns to normal. Adults with AATD, who had liver abnormalities as children, may be at increased risk to develop liver disease or liver cancer.

Researchers do not know exactly why some people with AATD develop liver disease while others do not. The chance that someone with AATD will develop liver disease is influenced by environmental factors and also the alleles that they have. For example, people with two ZZ alleles have a higher risk than someone with MZ or ZS alleles. The chance that someone with AATD and two Z alleles will develop significant liver disease is approximately one out of 10 (10%), and the chance that they will develop liver cancer

is approximately 2 out of 100 (2%). The risk of developing liver disease is also increased if an individual is male or diabetic or has a hepatic virus infection. People with AATD who have family members with liver disease or liver cancer are also at increased risk. An individual with repeated increased levels of liver enzymes is at increased risk for liver disease. AATD is the most common genetic cause of liver disease in infants and children.

Diagnosis

Testing should be considered in newborns with cholestatic jaundice, swollen abdomen, and poor feeding. In later childhood or adulthood, fatigue, poor appetite, swelling of the abdomen and legs, or abnormal liver tests may suggest the need for testing. Testing for AATD should also be done on any person with:

- chronic obstructive pulmonary disease
- unexplained chronic liver disease
- necrotizing panniculitis (raised bumps that develop into ulcers)
- granulomatosis with polyangiitis (inflammation of the blood vessels in the nose, sinuses, throat, lungs, and kidneys).
- unexplained bronchiectasis (permanent enlargement of parts of the airways of the lung)
- parents, siblings, children, or extended family members of individuals with an abnormal *SERPINA1* allele.

Some organizations recommend that individuals with asthma also be tested for AATD.

Testing for symptomatic individuals should include measurement of AAT in the blood and also testing for genetic variants. Measurement of protein levels alone is not sufficient, because the AAT level can fluctuate with inflammation or pregnancy, and in children. Levels of AAT in ZM and ZS individuals can be normal even though those people may be at risk for lung and liver disease. Although less common, PI typing to see whether the AAT is abnormal can also be done.

People without symptoms, who have family members with an abnormal *SERPINA1* allele, should undergo genetic testing. Genetic testing can test specifically for the most common allele variants (Z and S and sometimes F and I) or can look for any variations in the gene. Prenatal genetic diagnosis is available. It is recommended that the parents be tested first to see which alleles they have, to ensure accurate interpretation of results.

Lung disease in people with AATD is diagnosed by the same methods that are used to diagnose lung disease in those who do not have AATD. These studies include breathing tests such as total lung capacity and

pulmonary function tests. Total lung capacity, also called spirometry, is measured with a device called a spirometer. Pulmonary function tests measure oxygen/carbon dioxide exchange by determining the amount of air exhaled, the time to exhale, and the efficiency of oxygen transport. X-rays and other studies may also be performed. The initial evaluation should include complete lung function testing, which should be followed by at least yearly spirometry. A CT scan of the chest should be considered for people who have just been diagnosed and who have symptoms or abnormal pulmonary function testing.

Liver disease in children and adults with AATD is diagnosed by the same methods that are used to diagnose liver disease in people who do not have AATD. Liver function studies include tests measuring two liver proteins called serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT). SGOT is sometimes called aspartate transaminase (AST), and SGPT is sometimes called alanine aminotransferase (ALT). Studies may also look for deposits within the cells of the liver, called inclusions. Monitoring for liver disease should be done at least yearly and may include physical examination, including focused exam for signs of liver disease, liver ultrasound, and laboratory monitoring of AST, ALT, GGT, albumin, bilirubin, INR, and platelets.

Once the diagnosis of AATD has been made, it is important to share this information with relatives related by blood, especially parents, siblings, and children. These relatives may also have AATD and may want to have genetic testing. If they know that they have AATD before they develop lung disease, they can take preventative measures such as avoiding exposure to smoke and other lung toxins.

Treatment and management

Although AATD cannot be cured, proper management may prevent many of its serious consequences. People with AATD should not smoke cigarettes and should not be exposed to smoke or other lung irritants. Respiratory infections should be treated promptly, because they increase the level of harmful neutrophil elastase in the lungs. Some doctors recommend avoiding alcohol and oxidants; keeping hepatitis A and B, pneumococcal, and influenza vaccinations up to date; and preventing hepatitis C exposure.

Lung disease

The treatment of lung diseases caused by AATD is similar to the treatment of emphysema and lung disease from other causes. Short-acting bronchodilators may be

QUESTIONS TO ASK YOUR DOCTOR

- What other testing should I have done?
- How often should I undergo liver studies?
- What are the symptoms of liver disease?
- What *SERPINA1* gene variants do I have?
- What new treatments are available?

used to help maximize lung function, but these medications do not slow disease progression. Inhaled steroids may also help to control symptoms.

Protein augmentation

Treatment is available if individuals with AATD develop lung disease. One of the main treatments involves infusion of AAT protein concentrates, which are pooled, purified, human plasma protein replacement for the missing AAT. They may halt or slow progression of respiratory problems. Generally, the protein concentrate is infused into a vein weekly. Treatment with the replacement protein may not be effective if tissue damage to the lungs is severe. This is often called augmentation therapy. It is safe, and people who receive it have few adverse reactions. Results from the NIH patient registry and a comparison of Danish and German registries have been published. Both analyses suggest that augmentation therapy has beneficial effects. However, some researchers are not convinced that it is an effective treatment. Although the AAT concentrate is purified and screened for both HIV and hepatitis viruses, doctors recommend that patients undergoing this treatment receive immunization against hepatitis viruses.

Treatments in development

People with AATD have reason to be hopeful that effective treatments may be available soon. Researchers are studying an inhaled form of AAT concentrate and other biotechnology based treatments such as aerosols that deliver the normal gene to lung tissue.

Liver disease treatments

People with AATD and severe liver disease can be treated with a liver transplant. AATD with liver disease is a common reason for liver transplant in children. If the new liver is from a donor with normal AAT, it will have normal, functional protein after the transplant. Augmentation therapy (replacing the protein in the blood) does not effectively treat liver disease. Gene therapy for liver disease is not currently available.

Prognosis

Individuals with AATD who have never smoked nor been exposed to other respiratory irritants have the best prognosis. They might never develop lung disease, but if they do, the age of onset is usually later than that of smokers by 10 or more years. Prognosis is improved if people with AATD stop smoking before the onset of lung disease.

Lung disease in people with AATD typically progresses rapidly. Affected individuals may progress from decreased respiration during exertion to incapacitation within five years. Smoking cessation and prompt treatment are critical. Prompt treatment with replacement protein improves prognosis. Some scientists recommend delaying treatment until the affected person has quit smoking.

Prognosis of infants with liver disease is poor. However, if a donor is found, and the transplant is successful, the new liver has the *SERPINA1* alleles of the donor. In such cases, the prognosis related to AATD is very good.

A great deal of research is done on the prevention and cure of AATD. In 1997, 12 countries with registries of AATD patients formed an international registry, which has helped researchers to complete studies involving large numbers of patients. These studies are absolutely necessary to answer research questions, especially treatment questions. Pharmaceutical companies are also studying new treatment options.

Alpha-thalassemia X-linked intellectual disability syndrome

Definition

Alpha-thalassemia X-linked intellectual disability syndrome is a rare, inherited condition that usually only affects boys and is characterized by severe intellectual disability, characteristic facial features, and mild anemia.

Description

Alpha-thalassemia X-linked intellectual disability syndrome is also known as ATRX syndrome, X-linked intellectual disability hypotonic facies syndrome, and alpha-thalassemia/intellectual disability, X-linked. This condition is characterized by intellectual disability, severe developmental delay, unique head and facial features, skeletal abnormalities, poor muscle tone, and genital abnormalities. People with ATRX syndrome often have a form of mild anemia, called alpha thalassemia, resulting from a defect in the production of hemoglobin.

The distinguishing features of this rare disorder include severe intellectual disability and a distinctive facial appearance. Children with the syndrome also have clinical problems such as deformed joints or limbs, small kidneys, or abnormalities with how their bladders and other parts of the urinary tract form. Additionally, many children are born with a hole in their heart, as well as abnormalities in their gastrointestinal systems, such as bowel obstructions or problems with swallowing.

Genetic profile

Alpha-thalassemia X-linked intellectual disability syndrome is caused by pathogenic variants (mutations) in the *ATRX* gene, which is located on the X chromosome. More than 125 variants of the *ATRX* gene have been found in people who have alpha-thalassemia X-linked intellectual disability syndrome. Males only have one X chromosome, which they always inherit from their mother. Thus, males who inherit a variant in the *ATRX* gene are always affected with the disorder. Females who inherit a variant in the *ATRX* gene are carriers of the disorder. Carriers have one functional *ATRX* gene and one *ATRX* that has a variant. Female carriers rarely have signs of the condition, since they have one functional copy of the *ATRX* gene. Their mutated copy of the gene is usually inactivated in most cells. Some rare females have symptoms, because their mutated copy of the *ATRX* gene is not preferentially inactivated. Carrier females without preferential inactivation may also be at increased risk for bone cancer.

If a male is affected with alpha-thalassemia X-linked intellectual disability syndrome, it is impossible for him to reproduce because of genital abnormalities, such as testes that don't descend and other problems. Male children of female carriers of an *ATRX* variant have a 50% chance of inheriting the variant. Carrier females who bear children have a 25% of having a male who is affected with alpha-thalassemia X-linked intellectual disability syndrome, since there is a 50% chance that a child will be male (50% × 50%). Maternal aunts of a male with an *ATRX* variant may be carriers.

Sometimes the *ATRX* variant is a new (*de novo*) variant in the affected individual. In those cases, his mother is not a carrier. It is not known how often a *de novo* variant occurs in *ATRX*. The possibility of a *de novo* variant is unlikely if there are two or more affected brothers in the family. Testing for X-inactivation can sometimes help detect carrier mothers. If there are no other affected individuals in the family, and if the mother's X-inactivation studies are normal, then the variant is probably *de novo*, and the mother is unlikely to be a carrier. In that case, the recurrence risk to siblings is very small.

KEY TERMS

Amniocentesis—A prenatal test in which a hollow needle is inserted through the abdominal wall and into the uterus of a pregnant woman to obtain amniotic fluid containing cells from the fetus. These cells can be examined to determine the sex of the fetus or to look for genetic diseases.

Anemia—A condition in which the blood has too few red blood cells. As a result, tissues and organs do not get a sufficient amount of oxygen.

Chorionic villus sampling (CVS)—Biopsy of the placenta through the abdominal wall or by way of the vagina and uterine cervix to obtain fetal cells for the prenatal diagnosis of a genetic disorder.

Hemoglobin—A component of red blood cells that transports oxygen from the lungs to the tissues of the body.

Microcytic, hypochromic anemia—An anemia marked by too little hemoglobin and small red blood cells.

In other cases, a female may have germline mosaicism and appear not to be a carrier but have a child with an ATRX variant. In that case, the ATRX variant would be present only in the egg cells of the mother. Her blood cells would be normal, and therefore, X-inactivation studies and genetic testing would be normal. Since the ATRX variant is present in her egg cells, she will have an increased chance of passing the variant on to her offspring. The exact risk to offspring is hard to predict, since the number of affected eggs is unknown. Germline mosaicism cannot be tested for but would be suspected in a female who appears not to be a carrier but has multiple affected children. Males and females with germline variants may be at increased risk for bone cancer.

Demographics

The prevalence of alpha-thalassemia X-linked intellectual disability syndrome is not precisely known. More than 200 affected people have been identified worldwide. There are no reports of the condition being more common in specific ethnic groups or geographical regions, although more than 70 cases have been identified in Japan.

Signs and symptoms

There are distinctive features that accompany alpha-thalassemia X-linked intellectual disability syndrome. The most noticeable clinical signs are the severe

developmental delay and intellectual disability that is almost always present. From very early in life, affected individuals are delayed in meeting developmental milestones. Some fail to walk independently, and many do not learn to speak coherently. Poor muscle tone (hypotonia), which is also very common in this condition, plays a role in the developmental delay.

There are unique head and facial features associated with alpha-thalassemia X-linked intellectual disability syndrome. Affected individuals often have a small head (microcephaly); widely spaced eyes (telecanthus); a flat mid-facial area (mid-face hypoplasia); small and low-set ears; a small, triangular nose; a tented upper lip; and a full, everted lower lip with a protruding tongue. About two-thirds of affected individuals have short stature. In some patients, growth retardation is present throughout life, and in other cases, it begins around puberty. Other minor skeletal abnormalities have been observed as well, such as joint contractures, abnormalities of the fingers and toes, foot deformations, and scoliosis. Genitalia of affected individuals are often abnormal and underdeveloped. These abnormalities may be as negligible as undescended testes or as substantial as ambiguous genitalia appearing to be female in nature. In many cases, patients do not progress through a normal puberty, presumably due to inadequate amounts of the male hormone testosterone.

Patients with alpha-thalassemia X-linked intellectual disability syndrome can have abnormal digestion. Feeding problems are fairly common as well, such as swallowing difficulties, regurgitation of food, and/or vomiting. Constipation becomes an issue in some patients. These difficulties often resolve with age. Seizures occur in approximately one-third of cases. Cleft palate, deafness, cardiac defects, and renal/urinary abnormalities are less common but have been reported.

About 75% of the time, blood tests in affected individuals show a mild form of anemia, also known as alpha thalassemia, which results from a defect in the production of an important component of hemoglobin. However, this mild anemia does not appear to have any adverse consequences in patients with the disorder.

Diagnosis

Alpha-thalassemia X-linked intellectual disability syndrome can be suspected clinically in an individual who has intellectual disability; hypotonia; characteristic physical features such as craniofacial, skeletal, or genital abnormalities; and a family history consistent with X-linked recessive inheritance. Usually, the most obvious signs of the disorder are developmental delay, severely impaired cognitive function, and the characteristic facial

features. Magnetic resonance imaging (MRI) exams may show abnormalities in the white matter portion of the affected child's brain.

A clinical diagnosis is usually followed by genetic testing for variants in the *ATRX* gene. Genetic testing will detect variants in approximately 90% of individuals with alpha-thalassemia X-linked intellectual disability syndrome. This testing is usually done by looking for small variants and pieces missing and added in the entire *ATRX* gene. Since the clinical symptoms of alpha-thalassemia X-linked intellectual disability syndrome can overlap with other syndromes, sometimes genetic testing will include other genes. Once a variant is detected, testing can be done on the mother and other at-risk females.

If genetic testing uncovers a variant of unknown significance, then epigenetic signature analysis may be done to help confirm a diagnosis. This test looks for characteristic changes in the production of the protein produced by the *ATRX* gene that are usually found in affected individuals.

In some cases, blood abnormalities can be detected by various laboratory tests. For example, molecules called hemoglobin H (HbH) inclusions may be seen in the red blood cells of affected individuals. The presence of HbH is associated with alpha thalassemia. HbH inclusions are less helpful in identifying female carriers and are only seen in approximately 25% of women who carry an *ATRX* variant. Microcytic, hypochromic anemia can be detected by a blood test and may be a sign of alpha thalassemia X-linked intellectual disability syndrome. However, the absence of either of these blood abnormalities does not rule out this condition—many affected individuals will not demonstrate these abnormalities.

Another option for detecting female carriers of the *ATRX* gene is X-chromosome inactivation studies. In a typical female, each cell has two X chromosomes (X1 and X2), and one of them will be inactivated. This inactivation is a random process, meaning that there is a 50% chance that either one is affected. If one were to look at a significant number of cells, X1 would be inactivated in approximately the same number of cells as X2. This process is skewed in females who are carriers of the *ATRX* gene variant, because the X chromosome that carries the *ATRX* variant will be preferentially inactivated. A laboratory test can detect this skewed X inactivation. However, this characteristic is not always present in carriers of *ATRX* variants. It also can be present for other reasons. Thus, it is not diagnostic and must be interpreted in the context of the clinical findings and family history. X chromosome inactivation studies can be especially useful if molecular testing is not available or is uninformative in a family.

Prenatal testing is available for pregnancies that are at risk for alpha-thalassemia X-linked intellectual disability syndrome. For pregnancies in which the mother is a definite carrier of the *ATRX* variant, fetal sex is determined via cells obtained from amniocentesis or chorionic villus sampling (CVS). If the fetus is male, DNA from the fetal cells can be analyzed for the *ATRX* variant that has been found in the family. For pregnancies in which the mother has tested negative for the *ATRX* variant but has previously birthed an affected child, prenatal diagnosis should still be offered to all male fetuses, due to the possibility of germline mosaicism.

Treatment and management

Very few of the abnormalities that result from alpha-thalassemia X-linked intellectual disability syndrome are life-threatening. The anemia that often accompanies this condition is mild and does not require any treatment. In order to improve quality of life, a thorough clinical evaluation is recommended after the initial diagnosis. A growth evaluation of height, weight, and head circumference is recommended, as is a developmental assessment of motor, speech, cognitive skills. Early speech, physical, and occupational therapies, and special education are usually recommended. A neurological evaluation should include analysis of muscle tone and reflexes, and EEG and MRI if seizures are present. A genital exam can help assess whether surgery is necessary. A pediatric cardiologist can check for a hole in the heart that might require surgery. The eyes should be checked to make sure that they are not cross-eyed and that there are no other eye defects or vision problems.

The child should also have an evaluation of their feeding and gastrointestinal health. They should be evaluated for swallowing difficulties, aspiration risk, nutrition, reflux, vomiting, and bowel blockages. Feeding problems may need to be managed with tube feeding in the early months. In rare cases, a permanent feeding tube passed through the abdominal wall into the stomach can be used. An operation known as fundoplication may be necessary to correct problems with vomiting.

An assessment of the musculoskeletal system is also important. It will look at gross and fine motor skills to see whether physical and occupational therapy or adaptive devices like wheelchairs are needed. It will also look for problems with the spine, clubfoot, and problems moving the joints, which may require surgery or other therapies.

Prognosis

There is limited information on the prognosis for Alpha-thalassemia X-linked intellectual disability syndrome. The lifespan can be normal, but some children will die at an early age. One of the main causes of early death in this condition is pneumonia, which can

result from food entering the lungs due to vomiting and regurgitation problems.

Alport syndrome

Definition

Alport syndrome, also called familial nephritis, is an inheritable form of kidney disease. There are multiple distinct forms of kidney disease that are genetic disorders. The main inheritable types are Alport syndrome, autosomal recessive polycystic kidney disease, and autosomal dominant polycystic kidney disease. These are all forms

of kidney disease in which the nephrons, the basic functional units of the kidney, are diseased or damaged.

Description

Kidneys perform many important bodily functions. Having at least one kidney is necessary for life. Kidneys filter waste and extra fluid from the blood, keep a healthy blood level of electrolytes and minerals, help to maintain healthy blood pressure, and release hormones that are important for bodily functions. Normally, there are two fist-sized kidneys present, one on each side of the spinal column of the back just below the rib cage. Each kidney contains microscopic filter lobules called nephrons that transfer bodily waste products from the bloodstream to the urinary system. Healthy nephrons are critical for maintaining bodily functions, and the buildup of waste products can be life-threatening.

Alport syndrome is a genetic disease in which there is significant damage to the nephrons of the kidney. The disease is characterized by the onset of bloody urine in early childhood, which later leads to renal failure. The onset is typically in males before six years of age. After years of recurrent or persistent bloody urine, the kidneys begin to malfunction. Renal dysfunction typically occurs in the third or fourth decade of life, but occasionally before 20 years of age. Alport syndrome also involves progressive hearing loss and eye complications.

Genetic profile

The Mendelian genetic model demonstrates that an individual inherits two functional copies (alleles) of every non-sex linked gene. One copy is paternally inherited and the other is maternally inherited. When genes follow the Mendelian inheritance pattern, both the paternal and maternal copies are functionally expressed, regardless of which parent they came from.

There are different modes of inheritance for genetic disorders. An autosomal dominant mode of inheritance means that if one gene in the pair has a mutation, an individual will become affected with the disease. Since a parent only passes one copy of each gene on to their offspring, there is a 50%, or one in two, chance that a person who has autosomal dominant disorder will pass it on to each of their offspring. Males and females are equally likely to be affected in this mode of inheritance.

Autosomal recessive diseases are caused by the inheritance of two defective copies of a gene. Each parent may contribute one copy of autosomal genes to their offspring. In autosomal recessive inheritance, only if both copies are mutated does disease occur. If only one

defective copy is present, the disease does not occur, but the mutated gene can still be passed on to subsequent generations. If both parents are carrying a mutated gene, then each offspring has a 25% chance of inheriting the disease. Populations with a high frequency of healthy individuals carrying defective genes will also have higher prevalence of offspring with the disease.

The sex-linked chromosomes are denoted XX in females and XY in males. A female receives an X chromosome from each parent. A male receives the X chromosome maternally and the Y chromosome paternally. Some genetic disorders display X-linked recessive inheritance. In this mode of inheritance, mothers carrying defective X-linked genes can pass one copy to each offspring. However, because female offspring also receive a normal X-linked gene from the father, female offspring typically do not develop the disease. However, since male offspring receive their only X chromosome from the mother, if their mother carries the mutated X gene, the males can develop the disease.

Alport syndrome is a genetic disorder that can be inherited in different ways. The mode of inheritance is X-linked in 80% of cases, autosomal recessive in 15% of cases, and autosomal dominant in 5% of cases. Alport syndrome frequently affects the ears and eyes in addition to the kidneys. The inherited defect involves the basement membranes of the affected organs, as a result of mutations in type IV collagen genes. The basement membrane is a sheet-like structure made up of type IV collagen that supports the kidney cells. Type IV collagen is made up of six segments, called chains, designated A1 through A6. Each chain is encoded for by a distinct gene. These genes are distributed in pairs on three chromosomes. The A1 and A2 chains are encoded by the genes *COL4A1* and *COL4A2* on chromosome 13; the A3 and A4 chains are encoded by *COL4A3* and *COL4A4* on chromosome 2; and the A5 and A6 chains are encoded by *COL4A5* and *COL4A6* on the X chromosome. Alport syndrome involves mutations in the *COL4A3*, *COL4A4*, or *COL4A5* genes. All of the A chains encoded for by these genes are present in the basement membranes of the glomerulus (portion of the kidney that filters the blood), cochlea (portion of the ear involved with hearing), and the eye. Consequently, there are abnormalities in the basement membranes causing the symptoms associated with Alport syndrome.

Demographics

Estimates of the incidence of Alport syndrome vary and range from 1 in 5,000 to 10,000 to 50,000 individuals. It is believed to be under diagnosed. There is no distinction between ethnic populations. The X-linked form of Alport syndrome is the most common and predominantly

affects males. Further, there appears to be a relationship between the type and location of the mutation and the severity of disease. Females who carry the X-linked form of the condition typically have blood in their urine that does not cause symptoms. However, occasionally, other associated findings and severe renal disease may be present. The autosomal recessive and dominant forms of Alport syndrome are less common and affect both sexes equally.

Signs and symptoms

Alport syndrome usually has an onset of persistent microscopic bloody urine (hematuria). The amount of blood in the urine is too small to be detected visually, but can be detected in a laboratory test. For X-linked Alport syndrome, males typically present in early childhood with blood in their urine. The hematuria may last for many years and all males develop abnormal levels of protein in the urine (proteinuria), eventually resulting in renal dysfunction between 20 and 40 years of age. In autosomal recessive Alport syndrome, both males and females present in late childhood with hematuria and typically develop end stage renal disease in their 30s. End-stage renal disease occurs later in the autosomal dominant form of Alport syndrome.

Hearing loss is variable. It typically presents by or during adolescence and is progressive. However, in some families, hearing loss may present late in life. As with renal disease, hearing loss typically presents later with the autosomal dominant form of Alport syndrome.

Other associated complications may include abnormalities of the eye. These occur in about 1 in 3 individuals with X-linked and autosomal recessive Alport syndrome. The findings are rare in the autosomal dominant form. Anterior protrusion of the lens capsule and underlying cortex (lenticonus) is highly suggestive of Alport syndrome. Additionally, individuals may have dot and fleck retinopathy, corneal erosion, and a macular hole.

Diagnosis

Alport syndrome is diagnosed through multiple tests, including urinalysis, blood testing, family history, hearing and vision evaluation, kidney ultrasound, kidney and skin biopsies, and genetic testing. Urinalysis in individuals with Alport syndrome can identify microscopic or visible hematuria. The presence of high protein levels in the urine (proteinuria) is indicative of kidney disease. Proteinuria eventually develops in males with X-linked Alport syndrome, and in both sexes with the autosomal recessive form of the disease. Proteinuria usually becomes worse as kidney disease progresses. Blood tests

KEY TERMS

Amniotic fluid—The protective fluid surrounding a fetus in the womb.

Anemia—Condition in which there are low levels of red blood cells.

Asymptomatic—Without symptoms.

Computerized axial tomography (CAT) scan—An imaging technique that visualizes organs or tissues.

Cornea—The transparent, curved, fibrous coat of the front of the eye.

Creatinine—A normal component of blood kept in low levels in urine by functioning kidneys.

Dialysis—Filtering of blood to remove waste products that the kidneys would normally remove if they were present and functioning.

DNA—Deoxyribonucleic acid, inheritable material that constitutes the building blocks of life.

Locus (plural: loci)—Position occupied by a gene on a chromosome.

Mendelian genetics—A set of parameters describing the traditional method of the transmission of genes from one generation to the next.

Neonate—A newborn infant up to six weeks of age.

Nephron—Basic functional filtration unit of the kidney.

Oligohydramnios—An abnormally small amount of amniotic fluid.

Platelet—An important component of blood that forms clots to close wounds.

Pulmonary hypoplasia—Underdevelopment of the lungs.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

are also performed to look for standard protein markers of kidney dysfunction. If kidney disease has progressed, there may also be high cholesterol in the blood. Some cases of autosomal dominant Alport syndrome also have defects in platelets of the blood.

All children with a medical history that suggests Alport syndrome are tested for high-frequency hearing loss. To confirm a diagnosis of high-frequency hearing loss, a special tool called an audiometer is used. Eye complications can be diagnosed through an ophthalmologic examination.

Ultrasound imaging studies of the kidneys may be normal in the early stages of Alport disease. In the later stages of the disease, the kidneys may progressively decrease in size. A renal biopsy is performed to confirm the diagnosis. Physicians search for abnormalities in collagen indicative of Alport syndrome. The gene mutations that cause collagen abnormalities in the kidneys in Alport syndrome also cause similar collagen abnormalities in skin. For this reason, a skin biopsy may also be used. Skin biopsies are preferred if the patient has end-stage renal disease, in which case a renal biopsy may be unsafe. Genetic analysis is the only method by which to diagnose asymptomatic carrier females that carry an X-linked Alport syndrome gene. Genetic analysis is also the only method by which to make a prenatal diagnosis. It can also be used to make a definitive diagnosis when clinical findings or analysis of renal biopsy specimens is unclear.

Treatment and management

There is no treatment for Alport syndrome. The main therapeutic goal is to identify treatments that slow down or delay the onset of kidney disease. Several studies in mice have demonstrated that certain medications can slow down the loss of kidney function. These include angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs). Individuals with Alport syndrome who have taken angiotensin-converting enzyme (ACE) inhibitors while their kidney function was normal have been shown to develop kidney failure later. For end stage renal disease, the options are dialysis or a kidney transplant.

Other therapy treats the complications that arise as a result of Alport syndrome. Therapy includes erythropoietin for chronic anemia, medications that affect phosphate and vitamin D levels to combat bone loss, bicarbonate to correct acidic blood conditions, and antihypertensive therapy. Hearing aids may be used and individuals with corneal erosions may need to wear protective eyewear. Individuals should also avoid medications that are harmful to the kidneys, such as non-steroidal anti-inflammatory medications containing aspirin, ibuprofen and naproxen, as well as decongestants.

Prognosis

The prognosis for males with X-linked Alport syndrome and for all patients with autosomal recessive disease is poor. Most patients develop hypertension and end-stage renal disease. Deafness and visual loss may also be components of the poor prognosis. Many patients with a family history of juvenile-onset Alport syndrome or early-onset deafness usually develop end-stage renal disease by 20–30 years of age. In contrast, the prognosis for females with X-linked Alport syndrome is generally

good, with most having normal lifespans and clinically mild renal disease.

Alström syndrome

Definition

Alström syndrome is a very rare inherited human disorder that adversely affects several body organs and systems, including the eyes, ears, and heart.

Description

Alström syndrome is characterized by a progressive loss of vision and hearing, dilated cardiomyopathy (which is a type of heart disease that results in an enlarged and weakened heart muscle), obesity, type 2 diabetes mellitus, and short stature. Alström syndrome may also adversely affect the liver, kidneys, bladder, and lungs. Some persons with Alström syndrome have a skin condition, acanthosis nigricans, that causes body folds and creases of the skin to be thick, dark, and velvety. Carl-Henry Alström, a Swedish doctor, first described the syndrome in 1959.

The conditions associated with Alström syndrome may begin in infancy or early childhood, but some do not develop until later in life. There is considerable variability in degree and type of clinical conditions associated with individuals with Alström syndrome, even among affected siblings.

Persons with Alström syndrome have a similar level of intelligence as their family members. However, they may have learning difficulties due to vision and hearing losses that result in delayed early developmental milestones, academic difficulties, and problems with language skills. About 50% of persons with the syndrome exhibit such developmental delays.

Genetic profile

Alström syndrome is an inherited autosomal recessive disorder; that is, two copies of an abnormal non-sex-related gene, one inherited from each parent, must be present in order for the syndrome to develop. Alström syndrome can be inherited by both males and females with equal probability. A child born to parents who both carry an autosomal recessive gene mutation has a one-in-four chance of inheriting the malfunctioning genes from both parents and developing the syndrome. The child has a one-in-two chance of inheriting one abnormal gene and becoming a carrier. The parents, who each carry one copy of the inherited gene, do not show signs or symptoms of the syndrome.

The mutated gene responsible for Alström syndrome is *ALMS1*, which is located on chromosome 2. This gene is responsible for making a protein whose function is not well known. However, there is evidence that the protein is involved in hearing, vision, weight control regulation, and functioning of the heart, kidney, lungs, and liver. The *ALMS1* gene may also be involved in the regulation of insulin production by the pancreas, which controls blood sugar levels.

Studies of the *ALMS1* gene have shown that more than 80 mutations have been identified in persons with

Alström syndrome. Most of the mutations result in an abnormally small version of the ALMS1 protein that does not function properly. For example, a lack of normal ALMS1 function in the brain could result in the person overeating, or a loss of the normal ALMS1 protein in the pancreas could cause insulin resistance, resulting in obesity and diabetes, two common conditions associated with Alström syndrome.

Demographics

Alström syndrome is extremely rare, having been reported as affecting only about 800 people in 47 countries. It is more common in the Netherlands and Sweden than it is in the United States. Alström syndrome is sometimes confused with Bardet-Biedl syndrome, which has similar symptoms, although it typically develops later in life.

Signs and symptoms

Parents may first recognize symptoms of Alström syndrome by changes in their infant's eyesight between birth and fifteen months of age. The infant may exhibit sensitivity to light (photophobia) and a rapid movement of the eyes (nystagmus), which are caused by a slow degeneration of the cones of the retina. The cones are the photoreceptors that are used for seeing in well-lit environments. As Alström syndrome progresses, the rods in the eyes, which are responsible for capturing light in dimly lit environments, deteriorate. This retinal degeneration is called cone-rod dystrophy.

Up to 70% of persons with Alström syndrome begin to lose hearing in childhood (usually before they are 10 years of age) or as adults due to loss of nerve functioning in the auditory system, resulting in auditory information not being transferred to the brain. About half of all children with Alström syndrome have developmental delays.

Infants and toddlers with Alström syndrome, although born with normal birth weight, are usually overweight. However, by adulthood, weights of individuals with the syndrome may be in the high-normal to normal weight range. Individuals with Alström syndrome often have distinctive facial characteristics, including deep-set eyes with a rounded face, premature frontal balding, and thin hair, and they may have wide, thick, flat feet and short, stubby fingers and toes.

Type 2 diabetes mellitus may develop in individuals with Alström syndrome during the childhood or teenage years due to the development of insulin resistance. Insulin resistance is a condition in which the body's cells do not use insulin properly. Insulin, which is produced by the pancreas, helps cells use blood glucose for energy.

Complications from diabetes include amputation of limbs, blindness, heart disease, and kidney failure.

Diabetes insipidus may also develop in individuals with Alström syndrome. This is a condition characterized by frequent and heavy urination, excessive thirst, and an overall feeling of weakness. It may be caused by a defect in the pituitary gland or in the kidney. In this type of diabetes, there is no elevated blood sugar. Effects include interference with eating, appetite, weight gain, and growth. There may also be vomiting, diarrhea, and fever. Adequate intake of water is necessary to prevent dehydration and potassium loss.

An enlarged heart muscle associated with dilated cardiomyopathy can present in infancy or later during adolescence. Fluid and blood can accumulate in the lungs, resulting in shortness of breath. Fluids may also build up in the feet, ankles, and legs, causing congestive heart failure, in which case the heart is unable to maintain an adequate circulation of blood throughout the body. Up to 60% of persons with Alström syndrome develop heart failure as a result of dilated cardiomyopathy at some stage of their lives. Persons with Alström syndrome may also have elevated levels of cholesterol and triglycerides in their blood, which can also result in heart problems and stroke.

When children affected by Alström syndrome are in their late teens, they often start to exhibit problems with their kidneys and liver. Steatosis, or fatty liver, may develop due to excessive amounts of triglycerides and other fats accumulating inside the liver cells. There may also be elevated levels of enzymes in the liver. Effects on the liver may result in the development of portal hypertension, a condition in which the normal flow of blood through the liver is slowed or blocked by scarring or other damage. Progressive and chronic kidney disease may also develop. By adulthood (during the second to fourth decade of life), the liver and kidneys may start to fail and cause severe problems in those affected.

Additional conditions that may be associated with Alström syndrome include scoliosis (curvature of the spine) or kyphosis (a curving of the spine that causes a bowing of the back, leading to a hunchback or slouching posture), digestive and respiratory problems, high blood pressure, enlarged spleen, alopecia (loss of hair from the head or body) or hirsutism (excessive hairiness), low levels of growth hormone, advanced bone age, and an underactive thyroid. Persons with Alström syndrome may suffer from muscle dystonia, which causes involuntary movements and prolonged muscle contraction, resulting in twisting body motions, tremors, and abnormal posture; hyperuricemia (abnormally high levels of uric acid in the blood); frequent urinary tract infections;

kidney disease (advancing over time to kidney failure); digestive problems such as gastrointestinal reflux; and respiratory difficulties, such as chronic obstructive pulmonary disease (COPD), a progressive lung disease process characterized by wheezing, a chronic cough, and difficulties in breathing. Males with Alström syndrome may exhibit male hypogonadism, which is partial or complete failure of the genitalia to develop, while females with the syndrome may experience irregular menstrual patterns.

Diagnosis

Diagnosis of Alström syndrome is accomplished by clinical diagnosis, including blood tests, urine tests for presence of uric acid, eye exams for retinal degeneration, and hearing testing. Symptoms of diabetes, such as increased thirst or urination, also are used to diagnose the disease. Alström syndrome is usually not diagnosed in infancy, but is detected later by medical personnel as more symptoms develop through time. The syndrome is often not recognized until diabetes mellitus develops in the second or third decade of life. The diagnosis of Alström syndrome should be considered in infants if they exhibit cone-rod dystrophy, if their weight is above the 90th percentile, or if there is cardiomyopathy present.

Genetic diagnosis is not usually used, as testing is expensive.

Treatment and management

Alström syndrome has no specific treatment or cure. However, regular medical care is essential to manage all of the possible symptoms and conditions associated with the syndrome. Symptoms of the disorder must be treated as necessary, for example, with diabetes medications, hearing aids, or thyroid hormone replacement hormones, depending on the specific symptoms experienced by each individual patient.

Cardiac problems may require heart medications to remove excess fluids from body tissues, surgical intervention, or even heart transplantation.

Children experiencing cone-rod dystrophy can be aided with the use of enlarged-print reading materials, tinted glasses (with corrective prescriptions as needed), and magnifying tools such as monocular telescopes and electronic magnifiers.

Type 2 diabetes mellitus in persons with Alström syndrome may or may not require insulin treatments. A diet low in calories and refined carbohydrates may be sufficient to control the diabetes. High cholesterol and triglycerides may require the use of medications for control. A variety of medications may also be required in order to

KEY TERMS

Bardet-Biedl syndrome—A human genetic disorder that affects many body systems. It is characterized principally by obesity, retinitis pigmentosa (a type of progressive retinal dystrophy), polydactyly (having additional fingers or toes), intellectual disability, hypogonadism (a defect of the gonads that results in underproduction of testosterone), and possibly kidney failure.

Gastrointestinal reflux—A chronic condition in which acid from the stomach flows back into the lower esophagus, causing pain or tissue damage.

Genetic counseling—A short-term educational counseling process for individuals and families who have a genetic disease or who are at risk for such a disease. Genetic counseling provides patients with information about their condition and helps them make informed decisions.

Retina—Light-sensitive nerve tissue in the eye that converts images from the eye's optical system into electrical impulses that are sent along the optic nerve to the brain. The retina forms a thin membrane that lines the rear two-thirds of the eye.

manage symptoms involving kidney failure, liver problems, lung problems, and cardiomyopathy.

Increased exercise is useful for all persons with Alström syndrome. Yearly blood tests are recommended to screen for kidney or liver problems.

There is no known prevention for Alström syndrome. Based on family history and known cases of Alström syndrome in family members and ancestors, parents may seek genetic counseling to determine their risk of having a child with Alström syndrome. They may seek genetic testing to evaluate their *ALMS1* gene status and to determine whether both parents are carriers of Alström syndrome. Based on the results of genetic testing, parents may elect to adopt, become pregnant with egg or sperm from an unaffected known or unknown donor, prevent pregnancy, or terminate an affected fetus. Counseling will also help parents prepare for treatment and care of an affected infant after birth. Siblings of individuals with Alström syndrome may also wish to be tested in order to ascertain their risk of passing on the disorder to offspring.

Unfortunately, most families are not aware that both parents carry the mutated *ALMS1* gene until the birth of an affected child, as children with Alström syndrome are most often born to parents with no family history of the disease.

QUESTIONS TO ASK YOUR DOCTOR

- What symptoms and conditions do we need to watch for in our child?
- What types of medical specialties should we consult for our child's specific condition?
- What organizations and support groups are available?
- Where can we get genetic counseling for possible future pregnancies?

Prognosis

Alström syndrome is progressive, with affected children developing more symptoms as they get older. However, due to variability in the expression of various symptoms and conditions, the prognosis for individuals with the syndrome is also highly variable. However, the lifespan of patients with Alström syndrome rarely exceeds 40 years.

By the late teen years, children affected with Alström syndrome usually have little or no vision. They are also likely to develop deafness and type 2 diabetes. Kidney and liver failure will likely continue to worsen. Persons affected with Alström syndrome may also suffer from coronary heart disease, develop complications from diabetes, and exhibit fatigue and shortness of breath due to poor heart function.

Alzheimer's disease

Definition

Alzheimer's disease (AD) is an irreversible, progressive neurological disease caused by the degeneration and death of large numbers of neurons (nerve cells) in several areas of the brain, accompanied by diminished brain size. It is the most common form of dementia—the loss of cognitive functions. AD usually begins with short-term memory loss, followed by the progressive loss of memory and cognitive functioning, deterioration of physical functioning, incapacitation, and death. With growing numbers of people affected by AD, their increasing life expectancy, and the direct and indirect costs of their care, AD is a major public health concern.

Description

AD was first described by Alois Alzheimer (1864–1915), a German psychiatrist and neuroanatomist. While studying slides prepared from the brain of a 51-year-old woman who had died after suffering from dementia for several years, Alzheimer found abnormal clumps—now called beta-amyloid plaques—and bundles of fibers—now called neurofibrillary tangles. Because dementia was associated with the elderly, and Alzheimer's patient had been middle-aged, her disease was named presenile dementia and was thought to be very rare. It was not until the early 1950s that researchers came to realize that these plaques and tangles are the diagnostic signatures of AD—the single most common cause of dementia.

AD plaques are sticky clumps or clusters of dead and dying neurons and other cellular debris surrounding insoluble deposits of beta-amyloid. The latter are fragments of a larger protein called amyloid precursor protein (APP) that has not been properly processed. The plaques are situated among neurons and are believed to interfere with normal communication among neurons, eventually causing the nerve cells to die. The tangles are

Normal brain of a 70-year-old (left) and the brain of a 70-year-old with Alzheimer's disease (right). The right brain is atrophied.
(Jessica Wilson/Science Source)

accumulations of twisted fragments of tau proteins inside neurons. Tau proteins normally bind and stabilize neurons. When they are damaged by the addition of phosphate, in a process called hyperphosphorylation, they form filaments that twist around each other to form neurofibrillary tangles that can no longer stabilize the neurons. Increased beta-amyloid may cause the formation of neurofibrillary tangles. However, it is not known whether the plaques and tangles cause AD or are the result of it. They occur as part of the normal aging process but are far less prevalent in normal brains than in those of AD patients.

Scientists have found other changes in the brains of AD patients. Connections among nerve cells are disrupted, and nerve cells die in areas of the brain that are vital for memory and learning, including the hippocampus. The hippocampus is a structure deep in the brain that is essential for short-term memory. Later in the disease, the cerebral cortex is affected, particularly the areas responsible for language and reasoning. Eventually, many areas of the brain atrophy (i.e., become shrunken and dysfunctional).

Scientists also have observed that some neurons are more susceptible to AD-related changes than others,

producing the tangles of toxic tau proteins while other cells are able to resist these changes for years or even decades. In January 2021, researchers identified the neurons that are most vulnerable to the disease, distinguishing them from neighboring cells that appear to be more resilient. Using a technique called single-nucleus RNA sequencing, they were able to group neurons by patterns of gene activity and found that vulnerable cells expressed a protein called RORB. It is not yet known whether RORB itself causes the cells to be more vulnerable to tau. Scientists hope that further study will reveal how and why these cells accumulate tau proteins earlier than others in order to identify ways to make the cells more resilient, thereby slowing the spread of AD.

Levels of the brain neurotransmitters serotonin, norepinephrine, and acetylcholine are lower in AD. These chemicals transmit signals across the synapses or gaps among nerve cells. Many of the behavioral and psychiatric problems associated with AD are thought to result from low levels of these neurotransmitters. Acetylcholine and norepinephrine are also important for many other bodily processes, including digestion, blood vessel dilation and constriction, and regulation of the heartbeat.

There are other common causes of dementia besides AD, such as alcoholism and the overuse of drugs such as tranquilizers or pain relievers. Common causes of dementia also include multi-infarct vascular dementia, caused by strokes (blood clots in the brain). Vascular dementia can also be caused by diffuse white-matter disease that may result from multiple “mini-strokes.” Parkinson’s disease, which causes abnormalities in movement and functioning, also can cause dementia. Less common causes include thyroid dysfunction or other endocrine abnormalities, chronic infections, trauma or injury to the brain, brain tumors, psychiatric abnormalities, and certain other degenerative disorders. However, AD accounts for 50%–70% of all dementias and about 75% of all dementias in people over age 65.

Genetic profile

The causes of most cases of AD are unknown, although they are believed to be due to a combination of genetic and environmental factors. Most cases of AD are late-onset, developing after age 60–65. More than 75% of cases are sporadic—patients have no family history

of the disease. About 25% of AD cases are in patients who have family histories of AD. They may have inherited AD susceptibility or risk genes from their parents or may share environmental or lifestyle risk factors with family members. They may also share both genetic and environmental factors. Familial AD may be either early-onset or late-onset.

Early-onset AD

Early-onset AD develops between the ages of 30 and 60 and can be caused by inheriting one of three defective genes. Variant alleles or mutations in any of these three different genes result in the production of abnormal proteins that directly cause familial early-onset AD. Because these genes are located on chromosomes other than the X and Y sex chromosomes, they are called autosomal genes and affect males and females with equal frequency. A defective version of one of these genes, inherited from one parent, causes AD even if a normal version of the same gene is inherited from the other parent. Therefore, the defective gene is described as dominant. AD caused by one of these defective genes is known as

Alzheimer's disease: pedigree analysis chart (Gale)

The stages of Alzheimer's disease. The disease is characterized by the loss of neurons in the brain, leading to gradual atrophy of the cerebral cortex and loss of cognitive function. The illustration shows a series of coronal sections of the brain, depicting the shrinkage of the cerebral cortex and hippocampus, and the development of enlarged ventricles. (Evan Oto/Science Source)

autosomal dominant Alzheimer's disease (ADAD). Each child of a parent with one of these defective genes has a 50% risk of inheriting the gene and AD. If both parents have one copy of the mutant gene, each of their children has a 75% chance of inheriting at least one copy of it. Parents carrying two copies of the mutant gene will pass on the defective gene to all of their offspring.

All three of the abnormal proteins produced by these early-onset AD genes increase the amount of beta-amyloid in the brain.

- Mutations in the *APP* gene, located on chromosome 21, are associated with AD onset between the ages of 55 and 60, which is sometimes called AD1.
- Variations or mutations in the presenilin-1 (*PS-1*) gene on chromosome 14 are the most common cause of early-onset AD, sometimes referred to as AD3. PS-1 may be one of the enzymes that clip APP into beta-amyloid. It also may be important for the functioning of synaptic connections among neurons.
- AD4 is an extremely rare genetic defect in the presenilin-2 (*PS-2*) gene located on chromosome 1. Presenilin 2 is involved in processing APP.

AD-causing mutations in these “deterministic” genes are very rare, accounting for less than 5% of AD cases. They do not appear to be involved in late-onset AD. Since mutations in these genes account for only about 50% of early-onset familial AD, there are presumed to

be other as-yet-unidentified genes associated with early-onset AD.

Early-onset AD is also associated with Down syndrome—a genetic disorder caused by the presence of part or all of an extra chromosome 21. People over age 40 with Down syndrome develop the brain changes characteristic of AD. This is thought to be due to the overproduction of APP caused by the *APP* gene on the extra chromosome 21. Down syndrome-associated AD accounts for less than 1% of all AD cases.

Late-onset AD risk genes

As of 2021, genome-wide association studies have identified more than 30 genes and 200 different variants associated with late-onset AD. It is expected that more will be identified in the future. The presence of specific versions (alleles) of these genes or changes (mutations) in these genes may increase the risk of late-onset AD.

The gene with the strongest influence on AD is the apolipoprotein E (*APOE*) gene located on chromosome 19. Familial late-onset AD associated with the *APOE* gene is sometimes called AD2. The *APOE* gene codes for a protein that helps remove cholesterol from the blood. There are three common versions of *APOE*: *APOE-2*, *APOE-3*, and *APOE-4*. *APOE-2*, which is relatively rare, may provide some protection against AD. *APOE-3*, the most common *APOE* variant, does not appear to affect AD risk. *APOE-4* occurs in 10–15% of the population and in 40–60% of all people with late-

onset AD. People who inherit an *APOE-4* gene from one parent are at increased risk for AD. Those who inherit two copies of *APOE-4*—one from each parent—are at higher risk for AD. *APOE-4* may also cause AD at a younger-than-average age. Nevertheless, many people with one or two copies of *APOE-4* do not develop AD, and many people with AD do not have an *APOE-4* gene.

Other genes with variant alleles that have been associated with AD risk include:

- *AP4E1*, which plays a key role in brain development and functioning
- *AP4M1*, which encodes a subunit of a protein complex involved in intracellular transport of proteins that is thought to have a unique role in neurons
- *APBB3*, which encodes a protein that binds to the AD beta-amyloid precursor protein (APP)
- *BIN1*, which encodes a protein that interacts with tau protein
- *CLU*, which helps regulate clearance of beta-amyloid from the brain
- *CRI*, which encodes a protein that, when deficient, may contribute to chronic inflammation in the brain
- *MS4A4A* and *MS4A6A*, which alter levels of TREM2, a protein thought to help clear amyloid and tau from the brain
- *PICALM*, which is involved in communication among neurons
- *PILRA*, which encodes a protein involved in cell signaling pathways
- *RABEP1*, which encodes a protein involved in transport of the PKD1:PKD2 complex and membrane fusion
- *SORL1*, which is involved in regulating the transport of APP and lipoproteins
- *SPI1*, which encodes a protein that regulates several AD-associated genetic risk factors
- *TP53INP1*, which encodes two proteins that induce cell cycle arrest and cell death
- *TREM2*, which is involved in regulation of the response to inflammation in the brain
- *ZYX*, which encodes Zyxin, a protein located at sites of cell adhesion that regulates signaling in response to DNA damage

Other risk factors

- The most significant risk factor for AD is advancing age. The risk of developing AD begins to rise after age 65 and rises sharply after age 75.
- Head trauma—especially repeated trauma or serious injury with loss of consciousness—is strongly linked to increased AD risk.

- Conditions that damage the heart or blood vessels—including high blood pressure, heart disease, diabetes, and high cholesterol—increase the risk of both AD and vascular dementia.
- Strokes or other blood vessel damage in the brain appear to increase the risk that plaques and tangles will cause AD.
- Dietary fatty acids are associated with the development of AD, although probably only in people with APOE-4. This may be because higher consumption of fats increases cholesterol levels, which may lead to atherosclerosis in people with APOE-4. Atherosclerosis affecting blood vessels in the brain is an independent risk factor for AD.

Genetic testing

Genetic testing is available for early-onset AD genes and *APOE*. Most experts do not recommend *APOE* gene testing. People with APOE-4 do not necessarily develop AD, and people without APOE-4 may develop the disease. Furthermore, there is no preventive treatment for AD. In some cases, genetic testing for early-onset AD may be appropriate. For example, early diagnosis can lead to advanced planning and help to rule out other causes for symptoms.

Demographics

AD is the most common of all degenerative brain disorders. As of 2021, more than 6 million Americans were living with AD—nearly three-quarters of them are aged 75 and older. Deaths from AD more than doubled between 2000 and 2019. If current trends in AD incidence and life expectancy continue, it is estimated that by 2050, 12.7 million Americans aged 65 and over will have AD. Although two-thirds of Americans with AD are female, this is generally attributed to their longer life expectancy. African Americans and Latino Americans have higher rates of both vascular disease and AD than other racial and ethnic groups.

The incidence of AD in other developed countries with aging populations is similar to that in the United States. The risk of AD doubles every five years after age 65, to almost 50% in people over 85. Furthermore, AD is both underdiagnosed and misdiagnosed, at least until its late stages. It is estimated that at least half of affected people are unaware of their disease.

Signs and symptoms

Memory loss and other AD symptoms progress at different rates in different people. Some people may be unaware of their memory loss, a condition referred to as anosognosia. Others are keenly aware of their memory

KEY TERMS

Activities of daily living (ADL)—The skills and practices necessary for functioning in daily life and for participating in one's environment; progressively lost with Alzheimer's disease.

Allele—Any of the alternative versions of a gene that are present in the population.

Amyloid precursor protein (APP)—A protein that forms beta-amyloid in the brain when it is not correctly broken down; mutations in the APP gene can cause early-onset familial Alzheimer's disease.

Apolipoprotein E (APOE)—A protein that transports cholesterol and helps remove it from the bloodstream; the gene encoding one form of this protein, APOE-4, is associated with an increased risk of late-onset Alzheimer's disease.

Atherosclerosis—Thickening and hardening of the inner layer of the arteries due to the accumulation of plaque; a risk factor for Alzheimer's disease.

Autosomal dominant—A gene located on a chromosome other than the X or Y sex chromosomes that is expressed (translated into protein) in preference over a second copy of the same gene.

Beta-amyloid plaques—Senile plaques; dead or dying nerve cells and cell debris surrounding deposits of beta-amyloid protein in the brain; excess plaques are diagnostic of Alzheimer's disease.

Cholinesterase inhibitors—Drugs that may slow the progression of Alzheimer's disease by inhibiting the enzymes that break down the neurotransmitter acetylcholine.

Computed topography (CT)—Scans that use x rays and a computer to form detailed images of a part of the body such as the brain.

Dementia—A group of symptoms associated with chronic progressive impairment of memory, reasoning ability, cognitive functioning, personality

changes, deterioration in personal grooming, and disorientation.

Down syndrome—A genetic disorder characterized by an extra chromosome 21 (trisomy 21), mental retardation, and early-onset Alzheimer's disease.

Early-onset AD—Alzheimer's disease that develops between the ages of 30 and 60.

Familial—An inherited disease affecting multiple family members.

Late-onset AD—Alzheimer's disease that develops after age 65.

Magnetic resonance imaging (MRI)—An imaging technique that uses electromagnetic radiation and a computer to obtain detailed images of soft tissues such as the brain.

Neurofibrillary tangles—Accumulations of twisted tau protein fragments inside nerve cells in the brain that are diagnostic of Alzheimer's disease.

Neuron—Nerve cell.

Neurotransmitters—Chemicals that carry nerve impulses from one nerve cell to another; Alzheimer's disease causes a drop in the production of several important neurotransmitters.

Positron emission tomography; PET—A type of medical imaging that displays the metabolic activity of organs such as the brain.

Presenilin (PS-1 or PS-2)—Proteins involved in processing amyloid precursor protein; mutations in the genes encoding these proteins can cause early-onset familial Alzheimer's disease.

Single photon emission computed tomography; SPECT—An imaging technique for mapping brain function.

Tau—A protein involved in maintaining the internal structure of nerve cells; tau is damaged in Alzheimer's disease and forms neurofibrillary tangles.

loss and may become anxious and frustrated, which are common early-phase manifestations of AD. Eventually, memory loss starts to interfere with daily activities. Patients may also begin to experience disorientation and become confused by changes in their environment.

During the middle phase of AD, patients can easily become confused. Language difficulties develop, and patients experience problems with comprehension, remembering common names, or performing simple

mathematical calculations. Speech may not flow smoothly. Tasks such as dressing and preparing meals become difficult. However, some patients are able to continue routine behaviors and engage in generalized conversation during this phase. A small number of patients experience vision problems, but these are frequently denied and only confirmed after death when an autopsy indicates destruction of visual processing areas in the brain.

Late-stage AD patients require constant supervision. Those who can rise from bed may wander aimlessly and must be monitored at night, because sleeping patterns can become altered. However, muscle stiffening may make walking difficult. Patients are often unable to reason or demonstrate appropriate judgment. They may become uninhibited and confrontational. They may experience delusions—false beliefs despite ample evidence to the contrary—or hallucinations and may not recognize family members.

In the final stage of AD, patients need assistance with the simplest activities of daily living (ADL) such as feeding and dressing. A majority of patients are bedridden. Many are unable to talk and have lost bladder and bowel control. Abnormal jerking movements may occur, often precipitated by noise or touching. Reflexes are frequently exaggerated. Some patients experience whole-body contractions called generalized seizures.

Diagnosis

Although skilled physicians can diagnose probable AD with 90% accuracy, a definitive diagnosis is only possible by examination of brain tissue after death. Beta-amyloid plaques and intraneuronal neurofibrillary tangles normally occur with age but are greatly increased in AD. The pattern of increase is similar regardless of whether the AD is sporadic, familial early-onset, familial late-onset, or Down syndrome-related. In addition, the further the disease has progressed, the smaller the brain at death.

Despite the difficulties of definitive diagnosis, early and accurate diagnosis is important for developing strategies for managing symptoms. Additionally, helping patients and their families plan for treatment, long-term care, and financial concerns should be conducted while the patient can still be involved in decision-making. A diagnosis of AD also may help family members avoid unnecessary anger and feelings of helplessness when dealing with the progression of the disease.

Diagnosis is based on clinical findings of unexplained slowly progressing dementia when other causes have been ruled out. An accurate medical history is essential, including a family history of AD and ages of onset. Although neuroimaging alone cannot diagnose AD, positron emission tomography (PET), single photon emission computed tomography (SPECT), magnetic resonance imaging (MRI), or computed topography (CT) can reveal gross cerebral cortex atrophy (structural changes and shrinkage in the brain). The earliest changes in brain structure can be seen with PET scans. PET and SPECT scans can evaluate patterns of glucose (sugar) metabolism in the brain to differentiate patterns characteristic of AD

from those associated with vascular dementia and Pick's disease. PET scans are more precise than SPECT scans but are more expensive. MRI and CT scans are most useful in the early phase for excluding other brain abnormalities that may be causing dementia. As AD progresses, MRI and CT scans can show changes that indicate brain cell death. MRI is often performed on patients who are having problems with balance or gait and can detect diffuse atrophy in the cerebrum. Along with imaging studies, examination of cerebrospinal fluid has been used to confirm the diagnosis of AD.

In 2020, researchers reported accurate detection of amyloid and tau in the brain using a simple blood test. The test, which detects the presence of phosphorylated tau protein (p-tau181), a hallmark of AD, could be used to predict future AD, even in people without any symptoms at the time of the test. The affordable blood test also could help physicians monitor patients' responses to treatment to slow the progress of the disease.

Treatment and management

Although there is no cure for AD, early diagnosis and prompt intervention can slow its progression and enable patients to function independently for a longer period. Healthcare professionals usually assess a patient's ADL to determine the type of care that is needed. The mainstay of treatment is the establishment of daily routines, good nursing care and/or homecare strategies, and providing physical and emotional support. In the initial stages, counseling by a psychologist or an AD support group is recommended. The home environment must be made as safe as possible, and patients should be closely monitored to determine when they are no longer able to drive safely. Because disorientation is common, it is important to maintain a stable, familiar environment. Illnesses, such as urinary or respiratory infections, must be properly diagnosed and treated. Nutritional intake must be monitored, since patients will eventually become incapable of maintaining an adequate diet, and advancing age itself results in decreased appetite. Neurological and behavioral aspects of AD—including anxiety, agitation, defiant behavior, insomnia, hallucinations, and seizures—are treated on an as-needed basis.

Drugs

Medications may delay some AD symptoms and improve quality of life. Cholinesterase inhibitors—galantamine, rivastigmine, and donepezil—are prescribed for mild-to-moderate AD and may delay some symptoms or prevent them from worsening for a limited time. They may also help control some behavioral symptoms. Acetylcholine is a neurotransmitter that is important for memory and thinking. Cholinesterase inhibitors increase

QUESTIONS TO ASK YOUR DOCTOR

- Should I have genetic testing for Alzheimer's disease risk genes?
- Should my family members undergo genetic testing?
- Are there other tests for Alzheimer's disease?
- What form of Alzheimer's disease do I have?
- Are there treatments to slow the progression of Alzheimer's disease?

the amount of acetylcholine in the brain by preventing its breakdown. As AD progresses, the brain produces less and less acetylcholine, and the drugs become ineffective. Memantine is an N-methyl D-aspartate (NMDA) antagonist that lowers the amount of glutamate in the brain, since excess glutamate can cause brain cell death. Memantine is used to delay the progression of some symptoms of moderate-to-severe AD. It may help patients maintain some ADL, such as toileting, for a bit longer. However, all of these drugs are ineffective in many patients.

As of 2021 there were more than 1,700 active clinical trials of novel diagnostics and treatments for AD. Trials range from drugs targeting the beta amyloid protein and specific neurotransmitters to the use of transcranial ultrasound stimulation to relieve symptoms to studies assessing the effects of exercise, therapeutic diets, and caffeine on cognition.

In June 2021, the U.S. Food and Drug Administration (FDA) approved the drug aducanumab for the treatment of AD, after its own advisory panel had advised against approving the drug because it had found insufficient evidence of the drug's effectiveness. Aducanumab, an anti-amyloid-beta human monoclonal antibody, targets beta-amyloid and is intended to slow the progress of AD. Because it was fast-tracked for approval, Biogen, the drug's manufacturer, must conduct an additional randomized, controlled clinical trial to confirm Aducanumab's benefit. In addition to the controversy about its efficacy, the drug's price tag, \$56,000 per year, raises ethical questions about which patients will have access to it.

Medications can be prescribed to manage behavioral and psychiatric symptoms of AD that can be very stressful for caregivers. However, AD patients are more susceptible to the side effects of medications, especially psychoactive drugs, and they are usually given lower doses. Physicians often recommend first trying to reduce behavioral symptoms with changes to the patient's

environment. Drugs are usually prescribed for specific symptoms:

- typical antipsychotics—usually haloperidol, risperidone, olanzapine, or quetiapine—for anxiety, aggression, delusions, and hallucinations
- short-term anti-anxiety drugs—usually lorazepam or buspirone—for agitation
- a selective serotonin reuptake inhibitor (SSRI)—such as citalopram or sertraline at half the usual adult dosage—for depression, which is common in early-stage AD
- acetaminophen or very-low-dose codeine for pain

Prognosis

There is no cure for AD, and once symptoms develop patients do not recover. Although there is considerable variation in the rate of disease progression, symptoms continue to worsen, usually over a period of years. The goal is to maintain cognitive and physical functioning for as long as possible. Eventually, loss of brain cells and brain damage result in the impairment of autonomic body functions, the failure of various organ systems, coma, and death. Most AD patients die within eight to ten years of diagnosis, although survival can be as short as one year or as long as 20 years. The life expectancy of AD patients is increasing, because the disease is generally being diagnosed at an earlier stage.

Infection is the most common direct cause of death in AD patients. People with AD are often in poor health and may be malnourished, which puts them at increased risk for life-threatening infections such as pneumonia. They are also susceptible to other chronic conditions and diseases. The consequences of cancer, stroke, and heart disease can be more severe in patients with AD than in otherwise healthy people.

Ambiguous genitalia

Definition

Ambiguous genitalia is a congenital anomaly in which the genital organs do not appear to be male or female.

Description

Ambiguous genitalia, also called indeterminate sex and intersexuality, is a condition present at birth in which an individual has what appears to be both male and female external sex organs. This diagnosis is usually preliminary, based on an initial physical examination. After further evaluation and diagnostic procedures, specific genital anomalies are usually diagnosed and the underlying syndrome or condition that caused them identified.

When the genitals are abnormal, a genetic screening is usually performed to determine the genetic sex of the infant and to rule out chromosomal abnormalities.

In a genetic female with ambiguous genitalia, the clitoris may be enlarged, having the appearance of a small penis; the labia may be fused, resembling a scrotum; and the opening to the urinary tract may be located anywhere along the clitoris.

In a genetic male with ambiguous genitalia, the penis may be small, measuring less than .78 in. (2 cm); it can be mistaken for an enlarged clitoris. The clitoris often appears enlarged in newborns. The testicles may be undescended, a condition in which they remain inside the body, and they may have a groove or cleft resembling labia. The urinary tract opening may be located anywhere from the tip of the penis to any point along the underside, an anomaly known as hypospadias.

Ambiguous genitalia is not a medically threatening anomaly, but it can be an extremely emotional issue for parents. Often parents must decide in which gender the child will be raised. This is a complex and difficult decision. There are healthcare professionals who can help

inform and support parents. Counselors, doctors, and surgeons should be consulted before this decision is made.

The assignment of gender is not always based solely on the genetic sex of the child. When surgical treatment is necessary, parents may choose to raise a genetic male as a female because it is easier to surgically create functional female genitalia than male genitalia.

Children with ambiguous genitalia generally have one of the following conditions that cause the external genitalia to be abnormal:

- **Congenital adrenal hyperplasia:** This is the most common cause of ambiguous genitalia in infants. It is a condition affecting only females in which the fetus cannot process an enzyme called 21-hydroxylase, causing an inability to process steroids in the body. It is characterized by a genetic female with internal female sex organs and ambiguous or masculine external genitalia.
- **True hermaphroditism:** In this extremely rare condition, an individual has both ovarian and testicular tissue, the internal sex organs of both genders, external genitalia that are ambiguous or of both genders, and abnormalities of the X or Y chromosome.
- **Pseudohermaphroditism:** In this condition, the individual has ambiguous external genitalia, but the internal sex organs of only one gender.
- **Gonadal dysgenesis:** In this condition, an individual has the internal sex organs of a female, external genitalia that have characteristics of both genders but are predominantly female, abnormalities of the X or Y chromosome, and poorly developed ovaries or testicles.
- **Klinefelter syndrome:** This is a chromosomal abnormality in which males have an extra X chromosome. It is characterized by small testicles, infertility, and, in some cases, intellectual disability.

Genetic profile

The development of normal genitalia is a complex sequential process, beginning with the information stored on the X and Y chromosomes. Gonadal development in the fetus is first regulated by genetic information found on the short arm of the Y chromosome. Testis-determining factor (TDF) is a genetic sequence on the 11.3 sub-band of the Y chromosome. In the presence of TDF, testes develop. If TDF is absent, either because of a mutation of the Y chromosome or because the fetus is a female and therefore has no Y chromosome, then ovaries develop.

Testicular tissue produces two hormones essential for the development of normal male external genitalia: testosterone and müllerian-inhibiting substance (MIS). If

these hormones are present, the internal male sex organs develop. These hormones work in two ways. Testosterone promotes development of male genitalia, both external and internal, and MIS prevents the development of female internal sex organs. In the absence of these two hormones, female genitalia develop.

Until these hormones are produced, all external fetal genitalia are identical and resemble female genitalia. In males, around week eight of fetal development, testosterone and another hormone, dihydrotestosterone (DHT), cause the external sex organs to become those of a normal male.

Ambiguous genitalia as a condition is caused by an interruption in some part of this process. Such interruptions may be caused by genetic mutations; exposure to substances in utero, such as steroids; or, in very rare cases, maternal endocrine abnormalities.

The exact genetic or metabolic cause of ambiguous genitalia is determined by the underlying condition that leads to the anomaly. The following are the most common syndromes causing ambiguous genitalia:

- **Congenital adrenal hyperplasia,** the most common cause of abnormal external genital formation, is a defect in the production of the 21-hydroxylation enzyme. This is an autosomal recessive trait thought to be linked to the human leukocyte antigen (HLA) locus on chromosome 6, or more recently to Cytochrome P450 oxidoreductase deficiency.
- **True hermaphroditism** is extremely rare and involves development of both male and female internal and external genitalia. The most common karyotype of an individual with this condition is 46, XX. Researchers suspect that mosaicism is present and that a translocation of one antigen from a Y chromosome to one X chromosome or to an autosome may explain the development of male sex organs. True hermaphroditism does occur in individuals with a 46, XY karyotype. Explaining the development of ovarian tissue in this individual is difficult since two X chromosomes must be present for this to occur. Researchers theorize that there may be an undetected XX cell line within these individuals.
- **Pseudohermaphroditism** is generally caused by a failure in the production or absorption of the hormones testosterone and DHT. There are several different types of this condition, but they all appear to be passed on to the individual via either X-linked or autosomal recessive transmission. The anomalies are caused by a failure to produce sufficient levels of testosterone or a deficiency of enzymes, namely 5-alpha-reductase, necessary for DHT production.

- Individuals with gonadal dysgenesis have an abnormality of the sex chromosomes. Karyotypes often seen in these individuals are 46, XO/XY mosaicism and 46, XO.

Demographics

Ambiguous genitalia is a very rare condition. Researchers estimate that the most common cause, congenital adrenal hyperplasia, may occur in 1 of every 15,000 live births worldwide. Other conditions that affect the formation of external genitalia are even rarer.

Signs and symptoms

Primarily, ambiguous genitalia is a physical condition characterized by an abnormal appearance of the external genitals; however, the internal sex organs are typically malformed as well. There may be partially formed testes, ovaries, or both, or a complete absence of internal sex organs. Typically, individuals with ambiguous genitalia are infertile.

In some cases of pseudohermaphroditism, the genitalia may appear to be slightly abnormal but female at birth, but at puberty, the genitals may become more masculine as testosterone levels rise. What appeared to be an enlarged clitoris may develop into a penis of up to 2.7 in. (7 cm) in length.

The long-term health risks of this condition include an increased risk of tumors. Abnormal testicular tissue is vulnerable to tumor formation. As many as 40% of genetic males with ambiguous genitalia develop tumors within this tissue by the time they reach the age of 50. For this reason, regular screening is important.

Diagnosis

Ambiguous genitalia is usually diagnosed initially during a newborn's physical exam or during subsequent well-baby check-ups. Once it is suspected that the infant has abnormal genitalia, diagnostic tests may be performed to identify the child's genetic gender; the presence of a chromosomal abnormality; the presence, absence, and type of internal sex organs; and the potential for production of sex hormones.

Diagnostic tests that may be performed include the following:

- Chromosomal analysis to determine which sex chromosomes are present and if there are any abnormalities.
- Abdominal ultrasound to assess internal sex organs, if present, and to view the adrenal gland that is enlarged in females with congenital adrenal hyperplasia.
- Tests to assess the levels of male and female hormones present and the child's ability to process them; to determine if the infant can process enzymes; and to

KEY TERMS

Ambiguous—Unclear or open to more than one interpretation.

Autosome—One of the 22 chromosomes that are not involved in determining gender (chromosomes 1 through 22 and not the X or Y chromosome).

Clitoris—A small mass of erectile tissue in the female genitalia.

Congenital anomaly—An abnormality that is present at birth.

Genetic sex—The gender determined by the sex chromosomes. XX is female; XY is male.

Genitalia—The organs of reproduction.

Hypospadias—A birth defect in which the opening to the urinary tract, called the urethra, is located away from the tip of the penis.

Infertile—Incapable of reproduction.

Karyotype—A photographic representation of the full set of chromosomes numbered and arranged in pairs.

Labia—The two parts of the vulva (the external female genitalia).

Mosaicism—A condition in which an individual's cells are not all genetically identical.

Recessive—A genetic trait that is expressed only when present on both members of a pair of genes, one inherited from each parent.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosomal material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

X-linked—A genetic trait that is carried on the X chromosome.

screen for other metabolic conditions that may accompany ambiguous genitalia.

Treatment and management

Treatment of ambiguous genitalia depends on the extent of the abnormalities present, the underlying cause, and associated conditions. Treatment options include hormone replacement therapy (HRT) and surgical correction.

QUESTIONS TO ASK YOUR DOCTOR

- Will my child be able to have children of his or her own?
- Will my child have later psychological problems, particularly in sexual preference or gender identity?
- How many surgeries will my child need?

In some cases, gender assignment may be necessary. This can be a difficult and emotional decision for parents. Complicating the situation is the fact that when surgery is required to reconstruct external genitalia, the genetic sex of the child may not be the primary determining factor. It is far more difficult for surgeons to create functional male genitalia than female. For many years, it was thought that, in children for whom gender assignment surgery was considered the best treatment, a gender assignment should be made in the first few days of life. It was believed that environment or the influence of being raised as a girl or boy was enough to ensure gender identity. Recent data about individuals who were “assigned” a gender different from their genetic gender contradict this theory. Some individuals who were assigned a gender different from their genetic gender as infants and who were raised as the reassigned gender chose to assume the gender identity of their genetic gender as adults. Currently, many doctors believe that gender assignment involving surgical reconstruction of the external genitalia should be delayed until the individual has an established gender identity and can be involved in the decision.

Other factors that must be considered are issues of fertility, the ability of the internal sex organs to produce gender-appropriate sex hormones, the effects of sex hormone exposure on the fetus while in the womb, and the risk of additional health problems that may develop later in life either from HRT or internal sex organs.

Prognosis

If gender assignment is successful, the prognosis for children diagnosed with ambiguous genitalia is excellent. Depending on the underlying diagnosis and associated conditions, some additional medical management may be necessary. In children with congenital adrenal hyperplasia, steroid treatment is necessary for survival. Despite the complications from long-term steroid use, if the condition is properly diagnosed and treated, children with congenital adrenal hyperplasia can have healthy and normal lives.

Amelia

Definition

Amelia is an extremely rare birth defect marked by the absence of one or more limbs. The term may be modified to indicate the number of legs or arms missing at birth, such as tetra-amelia for the absence of all four limbs. A related term is meromelia, which is the partial

absence of a limb or limbs. Several older terms are no longer in use in international nomenclature because of their imprecision: phocomelia, peromelia, dysmelia, ectromelia, and hemimelia.

Description

The complete absence of an arm or leg in amelia occurs when the limb formation process is either prevented or interrupted very early in the developing embryo: between 24 and 36 days following fertilization. Nearly 25% of all congenital limb defects are amelia. A single limb is involved about 60% of the time, and symmetrical amelia is uncommon. The likelihood for upper versus lower limb absence varies with the syndrome.

Amelia may be present as an isolated defect, but more than 50% of the time it is associated with major malformations in other organ systems. The malformations most frequently seen with amelia include cleft lip and/or palate, body wall defects, malformed head, and defects of the neural tube, kidneys and diaphragm. Facial clefts may be accompanied by other facial anomalies such as abnormally small jaw, and missing ears or nose. The body wall defects allow internal organs to protrude through the abdomen. Head malformations may be minor to severe with a near absence of the brain. The diaphragm may be herniated or absent, and one or both kidneys may be small or absent.

Other abnormalities associated with amelia include severe defects of the lungs, vertebrae, heart, internal and external genital system, and anus. There is usually a severe growth deficiency, both before and after birth, and mental retardation may be present in survivors. Benign facial tumors made up of clusters of blood vessels (hemangiomas) may be present.

Amelia was traditionally thought to be a sporadic anomaly with little risk of recurrence, or evidence of genetic origins. However, an estimated 20% of amelia cases can now be traced to probable genetic causes. These genetic conditions may be due to recessive or dominant mutations, or involve chromosomal aberrations where entire sections of chromosomes are deleted, duplicated or exchanged. The best defined of these genetic diseases is known as Roberts SC phocomelia or, pseudothalidomide syndrome, caused by an autosomal recessive mutation of unknown location. There is a great variability of expression of the disease, even within families. Classic signs of Roberts SC phocomelia include symmetrical defects of all four limbs including amelia, severe growth deficiency, head and face (craniofacial) abnormalities such as small head and cleft lip or palate, also sparse, silvery blond hair, and facial hemangiomas.

A very small group of genetically based amelia cases is referred to as “autosomal recessive tetra-amelia” which consists of an absence of all four limbs, with small or absent lungs, cleft lip or palate, malformed head and other anomalies. A similar “X-linked tetra-amelia” is highly lethal to the fetus and involves the same set of abnormalities. The abnormal gene for X-linked tetra-amelia is assumed to be located on the X chromosome. Very few cases have been documented for either of these inherited conditions but the defective gene seems to be more prevalent in Arab populations of the Middle East or in small isolated cultures where consanguineous relationships (intermarriage within extended families) is more common. There is disagreement as to whether these conditions represent new syndromes or are severe cases of Roberts SC phocomelia.

Amelia is associated with various other genetic syndromes. It is seen in the autosomal recessive Baller-Gerold syndrome and Holt-Oram syndrome, an autosomal dominant condition that sometimes involves amelia. It has been proposed that many of the new, isolated cases of amelia are due to autosomal dominant mutations where only one copy of an abnormal gene on a non-sex chromosome is powerful enough to cause amelia to be displayed. Absent limbs have also been seen in chromosomal aberrations such as trisomy 8 (three copies of chromosome 8) and a deletion of region 7q22 found on the long arm of chromosome 7.

Sporadic amelia may be the end result of various types of disturbances of limb development in the embryo. These disturbances can be vascular, mechanical, due to teratogens (substances that can cause birth defects) or accompany other disease processes such as diabetes. An example of vascular disturbance would be hemorrhage in the embryo causing lack of blood and oxygen flow to surrounding tissue. The type and number of resulting defects would depend on the location of the hemorrhage and the point of embryo development when the bleed took place. Defects in limbs and the body wall tend to result from this type of disturbance.

Mechanical disruption can be seen following rupture of the amnion (the thin but tough membrane surrounding the embryo) due to infection, direct trauma such as attempted abortion or removal of IUD, or familial predisposition to rupture. Strands of the collapsed amnion and adhesions (fibrous bands, which abnormally connect tissue surfaces) may entangle and amputate developing limbs and cause a variety of other defects including facial clefts.

Various teratogens are well-established causes of amelia. A well-documented historic instance was due to thalidomide use by pregnant women from 1958 to 1963.

Thalidomide was used as a sedative and anti-nausea drug but was found to cause a wide array of limb deficiencies, including amelia. It is estimated to have caused 5,800 cases of malformed fetuses, mostly in Europe, but also in North America and wherever it was available worldwide. The mechanism by which thalidomide causes birth defects is still not known but may involve disruption of nerve processes. Although thalidomide is again in use today to treat certain cancers, infections and arthritis, it should not be used by women of childbearing age.

Alcohol (ethanol) consumption by pregnant women, especially in the first trimester, has been documented by several surveys to cause limb deformities. The abnormalities range from frequent, minor defects such as shortened fingers to the much rarer amelia. It is hypothesized that alcohol interrupts the blood supply to the developing limb resulting in malformation or non-growth. Additional teratogens known to cause amelia include methotrexate, other chemotherapeutic agents and potent vasoconstrictive drugs such as epinephrine and ergotamine.

Maternal diabetes mellitus (non-gestational) has long been associated with congenital anomalies, rarely including amelia. There is a two to threefold risk for congenital abnormalities in children of diabetic mothers and limb defects of various types occur in about one percent of infants of these mothers. It is thought that either abnormal maternal carbohydrate metabolism, or vascular disease resulting in decreased oxygen flow to the fetus, might play a role in causing malformations.

Genetic profile

Amelia is generally considered to be sporadic with scattered cases occurring infrequently. These rare events are presumably influenced by environmental factors, such as teratogenic drugs, maternal factors such as diabetes mellitus, and vascular accidents in the uterus. The role of genetics in causing this condition is still undetermined but two large epidemiological studies estimate that nearly 20% of amelia cases are of genetic origin. Mutations in more than one gene with different modes of transmission can lead to this severe limb deficiency.

Recurrence of amelia within families is the exception. When this occurs, it is most often associated with other malformations in autosomally recessive syndromes such as Roberts SC phocomelia, autosomal recessive amelia and X-linked amelia. Roberts SC phocomelia has a clearly identifiable genetic abnormality that can be seen during chromosome analysis. The abnormality is called either premature centromeric separation (PCS) or heterochromatin repulsion (HR). The darkly staining heterochromatin of the chromosome can be seen puffing and

KEY TERMS

Amnion—Thin, tough membrane surrounding the embryo and containing the amniotic fluid.

Autosomal dominant mutation—An abnormal gene on one of the 22 pairs of non-sex chromosomes that will display the defect when only one copy is inherited.

Autosomal recessive mutation—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Consanguineous—Sharing a common bloodline or ancestor.

Craniofacial—Relating to or involving both the head and the face.

Hemangioma—Benign tumor made up of clusters of newly formed blood vessels.

Homeotic genes—Developmental control genes active in the embryo.

Homozygous—Having two identical copies of a gene or chromosome.

Teratogen—Any drug, chemical, maternal disease, or exposure that can cause physical or functional defects in an exposed embryo or fetus.

X-linked mutation—An abnormal gene transmitted on the X chromosome.

splitting. The PCS test is positive in almost 80% of patients with Roberts SC phocomelia.

Demographics

The rarity of amelia makes the study of it on a population level speculative. A few large-scale studies pooling decades of information from malformation registries in several countries do provide preliminary data. Amelia has an incidence of 11–15 cases per million live births and 790 cases per million stillbirths. The condition is probably under reported due to lack of documentation of some miscarriages, stillbirths, and neonatal deaths.

There is no significant difference between number of males and females affected except in the select, extremely rare cases of X-linked amelia, which are all male. Only men would be affected, since the abnormal gene is inherited on the X chromosome and men only receive one copy of an X chromosome. Since females inherit two copies of the X chromosome, the normal copy of the gene on the second X chromosome can usually mask

the more severe complications that would result if only the abnormal gene was expressed.

The disorder occurs worldwide and there are no geographic clusters except for two. Amelia resulting from the use of thalidomide occurred primarily in Europe and other areas where the drug was available. Autosomal recessive and X-linked amelia has mostly occurred in Arabic and Turkish families. This suggests ethnic differences for an abnormal recessive gene but is based on less than 20 cases. Such a recessive gene is likely to be homozygous (meaning two copies of the abnormal gene need to be inherited for amelia to result), and thus expressed in malformation more often in any culture that tends to be isolated and has more intermarriage from a limited gene pool.

Signs and symptoms

Prior to clinical observation of absent limbs, certain signs in the pregnant mother may indicate a greater likelihood of amelia. Abnormal vaginal bleeding, diabetes mellitus, and toxemia (disturbed metabolism during pregnancy characterized by high blood pressure, swelling and protein in the urine) are all associated with amelia in the fetus. Alpha fetoprotein is a protein normally produced by the liver of the fetus which then circulates in the mother's blood. An increased alpha fetoprotein in the maternal blood may indicate neural tube defects that can accompany limb defects. Besides seeing missing limbs by ultrasound, signs in the fetus accompanying amelia include breech and other non-cephalic presentations at birth (where the baby is not in the normal head-first, face-down delivery position), an increased frequency of only a single artery in the umbilical cord, low placental weight and extremely low birth weight, not accounted for by the lack of limbs. The average birth weight for an infant with amelia is less than the third percentile for its age.

Diagnosis

Detection of an absent limb is generally simple. Clinical observation of the missing limb is either made at birth or prenatally by ultrasonography. However, more than 50% of amelia cases are accompanied by malformations of other organ systems, and in these cases, determination of a specific syndrome can be difficult. Defects overlap greatly between conditions. A family history including a pedigree chart to map other affected family members can be very helpful in detecting genetic causes. A prenatal history should include determination of maternal exposure to alcohol, thalidomide and other teratogenic drugs. Maternal diabetes mellitus should be considered a risk factor for congenital abnormalities.

QUESTIONS TO ASK YOUR DOCTOR

- What are my chances of having another baby with amelia?
- How can I reduce the risk of amelia in future pregnancies?
- What chromosome studies do you recommend?
- What are the risks of craniofacial surgery compared to the benefits?

Roberts SC phocomelia must be differentiated from other autosomal recessive or X-linked amelias. Genetic testing for PCS should be performed on cells from amniotic fluid. Darkly staining heterochromatin of the chromosome puffs out abnormally and splits in a positive test. The PCS test will be positive in nearly 80% of Roberts SC phocomelia cases but negative in the other syndromes. A positive PCS test along with some of the signs listed above, is diagnostic for Roberts SC phocomelia. Further chromosome studies should be done to detect gross chromosomal aberrations such as deletions or trisomy 8.

Treatment and management

Preventive measures to avoid serious limb defects such as amelia include avoidance of thalidomide and other teratogens in women of childbearing years, avoidance of alcohol during pregnancy and comprehensive management of diabetes mellitus throughout pregnancy. A prenatal ultrasound that detects an absence of limbs can be followed by chromosome analysis and genetic counseling to make informed decisions regarding termination.

Children with amelia can be fitted with a prosthesis to substitute for the missing limb. Surgery is often performed to repair craniofacial defects. Minimal to full time care may be needed depending on the degree of mental retardation.

Prognosis

When amelia occurs as an isolated abnormality, prognosis is good. However, when amelia is combined with multiple other defects, the prognosis is grim. Abnormalities accompanying amelia may include cleft lip and/or palate, body wall defects, malformed head, and abnormalities of the neural tube, kidneys and diaphragm. Many infants die prior to birth. 60% of newborns die within the first year, with half not surviving the first day. Mild cases of Roberts SC phocomelia are likely to survive past the

first few years and reach adulthood. Patients with more severe forms of amelia, such as severe growth deficiency and craniofacial defects, do not live past the first few months.

Amelogenesis imperfecta

Definition

Amelogenesis imperfecta (AI) is a genetic disorder of tooth development that occurs in at least 14 different forms. It may occur as an autosomal dominant, autosomal recessive, or X-linked disorder. The specific features of each type of the disorder vary significantly from type to type. The name of the disease comes from the fundamental problem involved, imperfect ("imperfecta") development of tooth enamel (amelogenesis). AI results in the improper development of both primary and permanent teeth.

Description

There are four categories of AI, defined by the primary symptoms associated with each. However, small, discolored, underdeveloped teeth—both primary and permanent—are characteristic of all categories. Due to

KEY TERMS

Autosomal dominant—A genetic trait that is expressed when only a single copy of a gene is present.

Autosomal recessive—A genetic trait that appears only when two copies of a mutated gene are present.

Dentin—A hard, calcareous material that covers the tooth root and, in turn, is covered by cementum and enamel.

Enamel—The hard, white coating that covers teeth. Enamel is the hardest material in the body.

X-linked—A genetic trait that is related to a gene on the X chromosome, characterized by transmission patterns that are different from those of autosomal traits.

insufficient development of the enamel, teeth are usually prone to pitting or breakage. Tooth loss, gum disease, and jaw misalignment may also occur.

Genetic profile

Some dental researchers estimate that there may be thousands of genes involved in the formation of dental enamel. Thus far, all forms of AI have been traced to mutations in just four genes, *AMELX*, *ENAM*, *MMP20*, and *KLK-4*. These mutations result in the body's failure to synthesize essential proteins required for the complex process by which adequate amounts of sufficiently strong enamel is produced, resulting in AI's characteristic features. The most abundant protein affected by gene mutations is amelogenin, whose production is controlled by the *AMELX* and *AMELY* genes (although the latter has not been implicated in mutations associated with AI). The precise role of amelogenin in enamel production is not known, although there is abundant evidence that loss of the protein results in significantly insufficient production of enamel in experimental animals and humans. Other proteins whose production is impaired by mutations are enamelin (*ENAM* gene), enamelysin (*MMP20* gene), and kallikrein 4 (*KLK-4* gene). Researchers suspect that mutations of the *AMBN* gene may be responsible for depleted quantities of the protein ameloblastin, the second most abundant protein involved in enamel synthesis.

AI may be inherited in at least four different ways, depending on the gene that has been altered. In most instances, the disorder occurs because of a mutation in the *ENAM* gene that is transmitted as an autosomal dominant trait, in which cases only a single copy of the gene is

needed to cause manifestation of the disorder. A mutation in either the *ENAM* or *MMP20* gene may also be transmitted as an autosomal recessive trait, in which cases two copies of the mutant gene are required for expression of the disorder. In about 5% of all cases, a mutation in the *AMELX* gene is transmitted as an X-linked trait. Finally, AI may result from a *de novo* (new) mutation in any one of these genes.

Demographics

Current data suggest a rather wide variability in the prevalence of AI, ranging from roughly 1 in 700 people in northern Sweden to 1 in 14,000 people in the United States. Data for prevalence in other populations are sparse.

Signs and symptoms

The 14 types of AI are grouped into four major categories, based on the primary development problem involved with enamel development:

- **Type I:** Hypoplastic AI is characterized by the production of an insufficient amount of enamel material to provide necessary protection for teeth. The disorder is transmitted as autosomal dominant, autosomal recessive, or an X-linked trait. Enamel varies from abnormally thin and smooth to normal thickness with pronounced grooves. Teeth may be insufficiently short to allow normal closure and may be colored anywhere from typically white and off-white to yellow or even brown.
- **Type II:** Hypomaturation AI occurs when enamel does not develop normally, and the tooth's structure may lack adequate amounts of crystalline material that constitutes its basic composition. The condition may also occur as autosomal dominant, autosomal recessive, or an X-linked trait. The condition is characterized by sufficient amounts of enamel that lacks normal strength, leading to frequent chipping and abrasion. Teeth may range in color from creamy white to yellowish brown and tend to be sensitive to touch and extremes in temperature.
- **Type III:** Hypocalcified AI is similar to type II AI in that it results from an inadequate development of calcium crystals that provide enamel with its typical strength. It occurs as an autosomal dominant or autosomal recessive trait. General features of the disorder are similar to those of type II AI, with frequent chipping and abrasion and color variations the dominant characteristics. Type II and type III AI are distinguished from each other on the basis of other morphological characteristics, such as contrasts between enamel and dentin.
- **Type IV:** Hypomaturation/hypoplastic/taurodontism AI is characterized by localized areas of low mineralization, resulting in the formation of pits in the teeth. The condition is transmitted only as an autosomal dominant trait. In addition to pitting, teeth tend to be foreshortened,

QUESTIONS TO ASK YOUR DOCTOR

- What kinds of treatment are available for each form of AI?
- How permanent can I expect any given treatment to be?
- At what point should I begin to consider starting treatments for AI?
- To what extent, if at all, does dental insurance cover the costs of treatments for AI?
- For each specific type of AI, which treatments are desirable, but not essential, (cosmetic) and which are essential to dental and general health?

abnormally small, and colored from milky white to yellow to brown.

Diagnosis

Diagnosis of AI is based on symptomatology of the condition, including the presence of thin, discolored, easily damaged teeth with indications of poorly developed and fragile enamel.

Treatment and management

The treatment of AI depends on the type of the disorder in question. In the case of type I AI, for example, sufficient amounts of enamel may not be present, although the strength of existing enamel may allow the installation of traditional crowns to produce teeth of adequate size. In the case of hypomineralized teeth, the enamel itself may be too weak and fragile to permit successful attachment of crowns, and tooth removal and replacement may be necessary. Series of treatments may be required for primary teeth during the period when both primary and permanent teeth are in place and again when all permanent teeth have erupted. Treatments may range in severity from relatively modest procedures to improve the appearance of the patient's mouth to extensive reconstruction needed to permit her or him to carry out normal daily procedures, such as mastication and maintaining oral hygiene. In more serious forms of AI, ancillary problems may develop that also require treatment, such as the development of gingivitis and malocclusions.

Prognosis

Treatments are generally available for all types of AI, with the result that prognosis is generally good for almost

all cases. Patients may expect improvements ranging from improved oral aesthetics to vastly improved dental structure and facility.

AI cannot be prevented, because it is a genetic disorder. It is possible to begin any one of a number of treatments, however, to prevent the condition from becoming worse and leading to other dental and general health problems. The precise treatment required depends on the type of AI a person has and its severity.

Amniocentesis

Definition

Amniocentesis is an optional procedure offered to women during pregnancy in order to obtain more information about a developing fetus. Women who undergo amniocentesis typically do so either to obtain reassurance

about fetal well-being or, if the results are abnormal, to plan for the remainder of their prenatal care.

Description

Amniocentesis is the most common invasive prenatal diagnosis technique offered to pregnant women. A doctor uses a thin, hollow needle to remove a small sample of amniotic fluid from around the developing baby. An ultrasound exam is usually performed at the same time to help guide the needle. The sample of amniotic fluid can be used to detect chromosomal abnormalities in a fetus, certain other types of congenital disorders, or other medical indicators. Tests done on amniotic fluid obtained by amniocentesis cannot evaluate the fetus for every potential kind of problem. The information it does provide, however, is very accurate, and it is generally considered the "gold standard" by which other prenatal diagnosis techniques are measured. The procedure is associated with a slightly increased chance of pregnancy loss.

The word "amniocentesis" is derived from the Greek words "amnion" and "kentesis," meaning "lamb" and "puncture," respectively. In order to perform the procedure, a doctor inserts a thin needle into the mother's uterus and the amniotic sac. A continuous ultrasound evaluation is typically used so that the doctor can avoid touching both the baby and the umbilical cord with the needle. The amniotic sac is made up of two membranes: the inner *amnion* and the outer *chorion*. The amnion and chorion both develop from the fertilized egg. They are initially separate but begin to fuse early in pregnancy. This fusion is usually completed by approximately the fourteenth to fifteenth week of pregnancy.

Amniocentesis is usually performed in the second trimester, usually during weeks 16 to 18 (mid-trimester). The amniotic sac holds the fetus suspended within the amniotic fluid, an almost colorless fluid that protects the fetus from harm, helps maintain a consistent temperature, and prevents the fetus, or parts of it, from becoming attached to the amnion. The amniotic fluid is produced and absorbed by the fetus throughout pregnancy. Fetal cells, primarily derived from the skin, digestive system, and urinary tract, are suspended within the fluid. A smaller number of cells from the amnion and placenta are also present. Finally, the fetus produces a number of different chemical substances that also pass into the amniotic fluid. These substances may be used, in some higher-risk pregnancies, either to assess fetal lung maturity or to determine whether the fetus has a viral infection. In the second trimester of pregnancy, one particular protein, called alpha-fetoprotein, is commonly used to screen for certain structural birth defects.

Amniocentesis (amniotic fluid test or AFT), a medical procedure in which a small amount of amniotic fluid, which contains fetal tissues, is sampled and tested for chromosomal abnormalities and fetal infections. (Monica Schroeder/Science Source)

It is possible to perform amniocentesis in a twin pregnancy. Amniocentesis in some higher-order pregnancies, such as triplets, has also been reported. In a multiple pregnancy, it is important to ensure that a separate sample of amniotic fluid is obtained from each fetus. To accomplish this, a doctor injects a small amount of harmless blue dye into the amniotic sac of the first baby after a sample has been withdrawn. The dye will temporarily tinge the fluid blue-green. A second needle is inserted into the next amniotic sac with ultrasound guidance. If the fluid withdrawn is pale yellow, a sample from the next fetus has been successfully obtained. In the case of monoamniotic (in one amniotic sac) twins or triplets, the genetic material in each fetus is identical, so only one sample needs to be taken.

Indications for amniocentesis

Amniocentesis has been considered a standard of obstetrical care since the 1970s. It is not, however, offered to all pregnant women. The American College of Obstetricians and Gynecologists (ACOG) recommends that

amniocentesis be offered to all expectant mothers aged 35 and older. This age cutoff has been selected because advancing maternal age is associated with an increasing risk of having a baby with a numerical chromosome abnormality. At age 35, this risk is approximately equivalent to the risk of pregnancy loss associated with amniocentesis.

A person normally has a total of 46 chromosomes in each cell of his or her body, with the exception of sperm or egg cells, which each have only 23. As women get older, there is an increased risk of producing an egg cell with an extra chromosome. This leads to an egg cell with 24 chromosomes rather than the normal 23. Pregnancies with an abnormal number of chromosomes are referred to as aneuploid. Aneuploidy results in a conceptus (product of conception) with either too much or too little genetic material. This, in turn, leads to abnormal development. Common effects of aneuploidy include an increased risk for pregnancy loss or, in live births, for intellectual disability and physical abnormalities.

Down syndrome is the most common form of aneuploidy in live born infants, occurring in approximately

1 in 700 births, regardless of maternal age. In women who are 35 years old, the risk of having a child with Down syndrome is higher, or roughly 1 in 385 at delivery. It is important to realize that Down syndrome is not the only chromosome abnormality that may occur. Other numerical abnormalities are possible, yielding genetic conditions that may be either more or less severe than Down syndrome. Thus, a woman is often given a risk, based solely on her age, of having a child with *any* type of chromosome abnormality. At age 35, this total risk is approximately 1 in 200. By age 40, this risk has increased to 1 in 65, and, at age 45, this risk is 1 in 20. These numbers reflect the risk at the time of delivery.

Women younger than 35 years may also have children with chromosomal or other genetic disorders. Therefore, other indications for amniocentesis or other forms of prenatal diagnosis include a family history of, or a previous child with, a known genetic condition; abnormal prenatal screening results, such as ultrasound or a blood test; or one parent with a previously identified structural chromosome rearrangement. All of these factors may make it more likely for a couple to have a child with a genetic condition.

Side effects

Women who have had an amniocentesis often describe it as uncomfortable, involving some mild pressure or pain as the needle is inserted. Fewer women describe it as extremely painful. A local anesthetic may be used to numb the upper layer of the mother's skin prior to testing. This medicine has no effect on the fetus, but it may help the mother feel more comfortable during the procedure. An experienced physician can, on average, perform amniocentesis in approximately one to two minutes.

Common complaints after amniocentesis include mild abdominal tenderness at the site of needle insertion or mild cramping. These usually go away within one or two days. More serious complications are significantly less common but include leakage of amniotic fluid, vaginal bleeding, or uterine infection. These complications are estimated to occur in fewer than 1% of pregnancies. In some women, complications after amniocentesis may lead to a miscarriage, or loss of the pregnancy. A woman's background risk of having a miscarriage, without amniocentesis, is approximately 2% to 3% in her

This doctor is using ultrasound as a guide to withdraw amniotic fluid, which is analyzed for chromosomal abnormalities. (Bork/Shutterstock)

KEY TERMS

Amnion—Thin, tough membrane surrounding the embryo and containing the amniotic fluid.

Anesthetic—A drug used to temporarily cause loss of sensation in an area of the body. An anesthetic may either be general, associated with a loss of consciousness, or local, affecting one area only without loss of consciousness. Anesthetics are administered via either inhalation or needle injection.

Chorion—The outer membrane of the amniotic sac. Chorionic villi develop from its outer surface early in pregnancy. The villi establish a physical connection with the wall of the uterus and eventually develop into the placenta.

Chromosome—A microscopic thread-like structure found within each cell of the body and consisting of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Conceptus—The products of conception, or the union of a sperm and egg cell at fertilization.

Cystic fibrosis (CF)—A respiratory disease characterized by chronic lung disease, pancreatic insufficiency, and an average age of survival of 20 years. Cystic fibrosis is caused by mutations in a gene on chromosome 7 that encode a transmembrane receptor.

Down syndrome—A genetic condition characterized by moderate to severe intellectual disability, a characteristic facial appearance, and, in some

individuals, abnormalities of some internal organs. Down syndrome is always caused by an extra copy of chromosome 21, or three rather than the normal two chromosomes. Therefore, Down syndrome is also known as trisomy 21.

Fetus—The term used to describe a developing human infant from approximately the third month of pregnancy until delivery. The term “embryo” is used prior to the third month.

Sickle cell disease—A chronic, inherited blood disorder characterized by sickle-shaped red blood cells. It occurs primarily in people of African descent and produces symptoms including episodic pain in the joints, fever, leg ulcers, and jaundice.

Tay-Sachs disease—An inherited biochemical disease caused by lack of a specific enzyme in the body. In classical Tay-Sachs disease, previously normal children become blind and mentally handicapped, develop seizures, and decline rapidly. Death often occurs between the ages of three and five years. Tay-Sachs disease is more common among individuals of eastern European Jewish background, but it has been reported in other ethnic groups as well.

Trimester—A three-month period. Human pregnancies are normally divided into three trimesters: first (conception to week 12), second (week 13 to week 24), and third (week 25 until delivery).

Uterus—A muscular, hollow organ of the female reproductive tract. The uterus contains and nourishes the embryo and fetus from the time the fertilized egg is implanted until birth.

second trimester. When performed by an experienced physician or technician, the risk for an amniocentesis-related pregnancy loss is estimated to be an additional 0.25% to 0.50%, or roughly 1 in every 200 to 400 pregnancies.

Much attention is often paid to the physical side effects of amniocentesis. However, it is important to also emphasize some of the emotional side effects. Many of these are applicable to other forms of prenatal diagnosis.

The offer of prenatal testing is associated with increased anxiety. This appears to be true whether a woman knew that prenatal testing would be offered to her during the pregnancy or if it came about unexpectedly, as is usually the case following abnormal screening results. Women to whom genetic amniocentesis is

presented must consider the perceived benefits of testing, such as the reassurance that comes when results are normal, and compare them to the possible risks. Potential risks include not only complications after testing but also learning that the child may have a serious disability or chronic medical condition.

The nature of the child’s possible diagnosis is also important. For example, it could lead to an early death, be more subtle, and cause few outward signs of a problem, or be somewhere in between. There are few treatments available to correct the hundreds of genetic disorders so far described. Couples may consider early termination of the pregnancy if a serious abnormality is detected. The definition of “serious” is often a matter of personal opinion. A couple’s value system and family

history, including other pregnancies and their outcomes, all influence the decision regarding amniocentesis. Ideally, a woman and her partner will have discussed at least some of these issues with each other and with either the woman's doctor or a genetic counselor prior to testing. The choice to have amniocentesis depends on many factors and should remain a personal decision.

Results

Genetic testing is available on amniotic fluid obtained by amniocentesis. The most common test result is a complete analysis of the fetal chromosomes. After a sample of amniotic fluid is obtained, the genetic laboratory isolates the cells, referred to as amniocytes, from the fluid. The cells are placed into two or more containers filled with liquid nutrients, establishing different cultures in which the cells will continue to grow. The cells are cultured anywhere between one and two weeks before the actual analysis begins, in order to synchronize the growth of the cells within a culture. Chromosomes are only microscopically visible at a specific point during cell division.

Once there appear to be an adequate number of cells to study, the cultures are harvested. Harvesting prevents additional cell growth and stops the cells at whatever point they were in their division process. A careful study of the total number and structure of the chromosomes within the cells may then be performed. Typically, chromosome results are available within 7 to 14 days after amniocentesis. Results may be delayed by a slowly growing culture, which rarely reflects an abnormal result but does extend the time until final results are ready.

Many laboratories are beginning to incorporate a special technique called fluorescence in situ hybridization (FISH) into their chromosome studies. This adjunct testing provides limited information about certain chromosomes within one to two days after amniocentesis. It does not replace a complete chromosome study using amniocyte cultures. In fact, FISH results are often reported as preliminary, pending confirmation by cultured results. They can, however, be very useful, particularly when there is already a high level of suspicion of a fetal chromosome abnormality.

FISH is performed using a small sample of uncultured amniotic fluid cells. Special molecular tags for particular chromosomes are used. These tags attach themselves to the chromosome. Under specific laboratory conditions, they can be made to "light up" or fluoresce. Their signals can then be counted using a special kind of microscope. FISH is most often used to quickly identify a change in the number of chromosomes from pairs 13, 18, 21, and the two sex chromosomes, X and Y. Abnormalities of these chromosomes account for nearly 95% of all chromosomal

QUESTIONS TO ASK YOUR DOCTOR

- In my specific case, do you recommend amniocentesis?
- How many amniocentesis procedures have you performed?
- What is my risk compared with the benefits of amniocentesis in my case?
- How long will it take to receive the results?

abnormalities. Other chromosomal abnormalities will be missed, since FISH cannot identify structural rearrangements of the chromosomes or abnormalities involving other pairs. A full chromosome evaluation on cultured cells is a necessary follow-up to interphase FISH results.

A sample of amniotic fluid may be used to measure alpha-fetoprotein (AFP). AFP is a protein made by the fetal liver. It passes out of the fetus and enters both the amniotic fluid and the mother's blood. Screening for open neural tube defects, abnormal openings in the fetal head or spinal cord, or ventral wall defects (openings along the belly wall) can be done by measuring AFP during the fifteenth to twentieth weeks of pregnancy. AFP levels normally show a gradual increase during this time. An unusually high level of serum AFP does not necessarily indicate a problem with fetal development, but it is cause for some concern. A high AFP level in amniotic fluid will detect up to 98% of all openings on the fetal body that are not covered by skin. Further studies may be suggested if the AFP is high. Most initial AFP results are available within two to three days after amniocentesis.

Finally, amniotic fluid samples obtained by amniocentesis may also be used for more specialized genetic studies, such as biochemical or DNA testing. Both often require cell cultures and additional time to complete. These studies are not done on every sample. Rather, they are offered to those couples who, based on their family history or other information, are at increased risk of having a child with a single gene, or Mendelian, disorder. Hundreds of such disorders have been described. Examples include Tay-Sachs disease, cystic fibrosis, and sickle cell disease. If biochemical or DNA studies are performed, all of the results may not be ready until three to four weeks after testing, although the waiting time may be slightly different for each patient.

It is important to emphasize that normal results from tests done on amniotic fluid do not necessarily guarantee the birth of a normal infant. Each couple in the general

population faces a risk of roughly 3% to 4% of having a child with any type of congenital birth defect. Many of these will not be detected with tests done on amniotic fluid samples obtained by amniocentesis. Babies with birth defects are often born into families with no history of genetic disorders.

Chorionic villus sampling

Mid-trimester amniocentesis has been available for nearly 30 years. Chorionic villus sampling (CVS) has been available in the United States since the 1980s. CVS is usually performed between 11 and 14 weeks of pregnancy. Chorionic villi are tiny finger-like projections on the placenta that contain some fetal cells. This material can be extracted for genetic analysis between weeks 11 and 14 of pregnancy. As of 2021, the risk of miscarriage from performing chorionic villus sampling is close to the risk with amniocentesis. Chorionic villus sampling can give results earlier in pregnancy, but it cannot detect certain fetal abnormalities (such as neural tube defects) that are detectable with amniocentesis. The pros of cons of both procedures should be discussed with the woman's physician to determine which will most effectively address her concerns.

Early amniocentesis

The Canadian early and mid-trimester amniocentesis trial (CEMAT), a large multi-center randomized clinical trial of early amniocentesis in the late 1990s, was designed to examine and compare the safety and accuracy of early (EA) versus mid-trimester amniocentesis (MTA). In order to accomplish this, 4,374 pregnant women were identified and enrolled in the study. Ultrasound was performed in the first trimester to confirm the gestational age of all pregnancies. Computer randomization was used to evenly divide the women into either the EA or MTA groups. Ultimately, 1,916 women underwent EA, and 1,775 women had MTA. Follow-up was obtained on nearly all pregnancies. Two striking conclusions were reached: EA is associated with an increased incidence of clubfoot and an increased risk of procedure-related pregnancy loss.

Amyloidosis

Definition

Amyloidosis is the name of a group of diseases caused by the deposition of abnormal proteins called amyloids in different tissues or organs of the body, resulting in the loss of normal function in these tissues or organs. Some physicians prefer to use the plural form "amyloidoses" to refer to these disorders because they are caused by different amyloids, they have a wide range of clinical symptoms, and they have different origins—some are hereditary, while others are acquired. All of the amyloidoses are rare disorders.

Description

The classification of the amyloidoses has undergone considerable change in recent years due to the discovery of the many different types of amyloid protein. In general, the term "amyloid" refers to misfolded proteins that form insoluble waxy fibrils in body tissues or organs. The name comes from the Greek word for starch because German pathologist Rudolf Virchow, the first person to

Amyloid deposits in the glomeruli of kidney. (Vetpathologist/Shutterstock)

identify amyloid under a microscope, mistakenly believed it was a form of starch. Until the 1970s, amyloid was thought to be a single type of protein; however, the discovery of various chemical techniques for dissolving amyloid fibrils led to the recognition that there are at least 27 different types of amyloids in humans.

Two different classification systems for the amyloidoses were used as of 2015, the older system based on clinical presentation and the newer and preferred system based on the type of amyloid involved. Some physicians still use the clinical classification system, which divides the amyloidoses into primary (occurring without any connection to another disease process), secondary (resulting from an existing disease), and familial (hereditary). This system also distinguishes between systemic amyloidoses, which affect the entire body, and localized amyloidoses, which are limited to one region of the body.

The newer system of classification categorizes the amyloidoses according to the type of amyloid that causes the disorder. Each type begins with the capital letter A for amyloid, followed by a second letter or abbreviation that identifies the type of protein in the fibrils. The three most common types of amyloidosis are AL, AA, and ATTR, or AF, amyloidosis. The third type is the most common type of amyloidosis associated with a genetic mutation.

- **AL amyloidosis:** Also known as amyloid light-chain amyloidosis, AL is a primary amyloidosis and is the most common type of systemic amyloidosis diagnosed in the United States. It develops when the antibody-producing white blood cells (called plasma cells) derived from the bone marrow form abnormal proteins made up of antibody fragments called light chains. These light chains then form amyloid deposits in such organs as the kidneys, liver, spleen, heart, digestive tract, and blood vessels. AL amyloidosis may occur together with malignancies such as multiple myeloma or lymphoma.

- **AA amyloidosis:** AA amyloidosis is a secondary amyloidosis caused by the accumulation of abnormal serum amyloid A protein, which is normally produced in the body during the acute phase of response to inflammation. It is sometimes called autoimmune amyloidosis. Patients with such long-term inflammatory disorders as Crohn's disease, rheumatoid arthritis, familial Mediterranean fever, tuberculosis, lupus, ankylosing spondylitis, and certain types of cancer are at increased risk of AA amyloidosis. The amyloid deposits in this type of amyloidosis are most likely to occur in the kidneys, liver, and spleen. More than 90% of patients with AA amyloidosis develop nephrotic syndrome, a kidney disorder.

- **ATTR (AF) amyloidosis:** Also known as familial amyloidosis or AF, ATTR is the most common form of amyloidosis associated with a genetic mutation. The gene involved is the *TTR* gene on the long arm of chromosome 18 at 18q11-q12. This gene codes for a protein found in blood serum and cerebrospinal fluid called transthyretin, which serves as a carrier of the thyroid hormone thyroxine. ATTR amyloidosis includes several types of familial amyloid polyneuropathy (FAP) formerly classified by the patients' ethnic origins. FAP is characterized by damage to the nerves in the arms and legs, carpal tunnel syndrome, cardiomyopathy, digestive disturbances, visual disturbances, and amyloid deposits in the brain stem and spinal cord. These symptoms typically appear in middle-aged or older adults. More than 100 mutations of the *TTR* gene have been identified; most of them cause ATTR amyloidosis.

Less common types of amyloidosis include the following:

- **Beta2-microglobulin amyloidosis (Abeta2m):** This is a relatively rare type of amyloidosis; it is also called dialysis-related amyloidosis because it occurs primarily in patients undergoing hemodialysis over long periods of time (usually five years or longer). Long-term treatment of kidney disorders with hemodialysis results in the buildup of a protein in blood serum called beta2-microglobulin. This protein accumulates in the patient's blood because it cannot cross the filter in the dialysis machine. It forms into amyloid fibrils that are deposited in the patient's joints.
- **Hereditary visceral (renal) amyloidoses:** These are rare forms of amyloidosis caused by mutations in three different genes on chromosomes 4, 11, and 12, respectively. They are sometimes called *Ostertag* amyloidosis after the German physician who identified the first case in 1932. These amyloidoses are grouped together as familial visceral amyloidoses. They are characterized by enlargement of the liver and spleen (hepatosplenomegaly), hypertension, edema, kidney

dysfunction, high levels of blood and protein in the urine, and generalized weakness. Unlike TTR-related hereditary amyloidosis, these familial amyloidoses are not marked by disorders in the peripheral nervous system.

- **Localized amyloidoses (ALoc):** Localized amyloidoses are a variant form of light-chain amyloidosis, except that the plasma cells that produce the abnormal proteins are found in the affected tissues rather than in the bone marrow. The amyloid deposits resemble tumors and are most commonly found in the bladder or the airway, but they may also occur in the eyes, skin, digestive tract, or breasts.

Genetic profile

Most amyloidoses are not hereditary. Those that are caused by genetic mutations are autosomal dominant in inheritance pattern, which means that only one copy of the mutated gene is required for the disorder to manifest. Men and women are equally affected. Most cases of amyloidosis associated with a genetic mutation are caused by mutations in the TTR gene on the long arm of chromosome 18. Mutations in this gene are found in most ethnic groups worldwide.

The hereditary visceral amyloidoses are caused by mutations in one of three genes: the FGA gene on the long arm of chromosome 4 at 4q31.3, the APOA1 gene on the long arm of chromosome 11 at 11q23.3, and the LYZ gene on the long arm of chromosome 12 at 12q15. The role of mutations in these genes and the formation of abnormal amyloid proteins were not well understood as of 2015.

Demographics

The amyloidoses as a group are rare disorders, affecting between 2,500 and 4,000 people in the United States each year. Most of these are patients diagnosed with AL amyloidosis. AA amyloidosis and the hereditary amyloidoses are much less common in the developed countries; however, AA amyloidosis is the most common form of the disorder in the developing world. Although the amyloidoses are thought to affect men and women equally, about 60% of the patients seen in specialized amyloid clinics are males. Most patients are between 50 and 65 years of age at the time of diagnosis. Amyloidosis is almost never seen in children, the exception being children with Crohn's disease.

Hereditary amyloidosis associated with mutations in the TTR gene occurs in about 1 in every 100,000 Caucasian persons in the United States; the rate in the African-American population is 4 in every 100,000. Transthyretin-associated amyloidosis has been reported

KEY TERMS

Amyloid—Any of a group of insoluble abnormal proteins that accumulate in body organs and tissues and interfere with their normal functioning.

Cardiomyopathy—Measurable deterioration of the heart muscle's ability to contract normally, eventually leading to heart failure.

Dyspnea—Shortness of breath or difficulty in breathing.

Goiter—An enlargement of the thyroid gland, causing tissue swelling that may be seen and/or felt in the front of the neck. It may occur in people who have overactive production of thyroid hormones (hyperthyroidism), decreased production of thyroid hormones (hypothyroidism), or normal production of thyroid hormones.

Light chains—The two small polypeptide chains found in an immunoglobulin (antibody) molecule. The other two components of the antibody are so-called heavy chains.

Macroglossia—Abnormal enlargement or thickening of the tongue.

Nephrotic syndrome—A kidney disorder characterized by high levels of protein in the urine, low levels of albumin in the blood, and edema (abnormal accumulation of fluid in the body). It may be caused by genetic mutations, infections, certain medications, or such other disorders as diabetes and cancer.

Periorbital purpura—A purplish or brownish discoloration caused by bleeding from the fragile capillaries in the skin around the eyes.

Peripheral neuropathy—Any disease of the nerves outside of the spinal cord, usually resulting in weakness and/or numbness.

Plasma cells—White blood cells that originate in the bone marrow and secrete large quantities of antibodies.

in families in Greece, Portugal, Finland, France, Germany, Sweden, Spain, Ireland, and Japan. Patients with TTR-associated amyloidosis may develop symptoms as early as 30 years of age.

Hereditary visceral amyloidosis may be more common than is usually thought; one study in the United Kingdom reported that about 5% of patients being treated for AL amyloidosis were found to have a genetic mutation associated with hereditary visceral amyloidosis.

Most families identified with this type of amyloidosis are of northern European ancestry, but the mutations have also been reported in families from northern India, Peru, Korea, and Mexico. Most of the cases reported in the United States have been identified in African American families.

Signs and symptoms

The signs and symptoms of amyloidosis are seen (with very rare exceptions) only in adults. They vary widely in body location and severity, depending on which organs or tissues are affected. The amyloidoses can be difficult to diagnose because none of the symptoms of these disorders is unique to them. Symptoms that may indicate amyloidosis are as follows:

- **Kidneys:** The kidneys are the organ most likely to be affected by AL, AA, ATTR, and hereditary visceral amyloidosis. Symptoms may include slight enlargement of the kidneys, complete shutdown of kidney function, or foamy urine (a sign of large amounts of protein in the urine).
- **Digestive system:** Constipation or diarrhea, unexplained weight loss, feeling of unusual fullness after a meal, gastrointestinal reflux disease (GERD), clay-colored stools, and unusual thickening of the tongue (macroglossia).
- **Liver:** Abnormal enlargement of the liver (hepatomegaly) and elevated levels of serum aminotransferases and alkaline phosphatase, which are biomarkers of liver injury.
- **Heart:** Abnormal EKG readings, abnormal heart rhythms, and heart failure.
- **Thyroid gland:** Unusual fatigue, low levels of thyroid hormone (hypothyroidism), and goiter.
- **Lungs:** Difficulty breathing or shortness of breath (dyspnea).
- **Nervous system:** Numbness, tingling sensations, or weakness (peripheral neuropathy) in the arms and legs; carpal tunnel syndrome in the arms.
- **Skin:** Bleeding into the skin around the eyes (periorbital purpura) leading to a “raccoon eyes” appearance.

Diagnosis

The diagnosis of the type of amyloidosis is critical, as effective treatment depends on identifying the type of amyloid responsible for the patient’s symptoms. The basic diagnosis of amyloidosis is made from a tissue biopsy, in most cases a sample of tissue taken from abdominal fat through a biopsy needle inserted into the skin over the abdomen. If the patient’s symptoms suggest amyloidosis in other organs, however, the tissue sample may be taken from those organs. The next step is staining the biopsy sample with Congo red, a dye that colors

QUESTIONS TO ASK YOUR DOCTOR

- What type of amyloidosis do I have?
- If I have a hereditary form of amyloidosis, would you recommend genetic testing for other family members?
- What treatment do you recommend?
- What is the prognosis?

amyloid protein and also causes it to look green when the slide is viewed under a microscope with polarized light.

Because AL amyloidosis is the most common type of amyloidosis in the United States, further testing is done to either confirm its identification or rule it out. The tests most commonly used are tests for free light chains in the blood serum or a bone marrow biopsy with immunochemical staining of plasma cells. The most accurate method for distinguishing among the different types of amyloid that may be causing the patient’s symptoms is laser microdissection with mass spectrometry. In this method, the laboratory technician uses a laser to dissect Congo red-stained biopsy samples that have already tested positive for amyloid. This process breaks down the sample into smaller units of amino acids called peptides. The peptides can then be analyzed by liquid chromatography-mass spectrometry.

The imaging study most often done in patients with amyloidosis is ultrasound. Sound waves are reflected differently from amyloid deposits than from normal tissue. In addition, ultrasound is useful in detecting abnormal enlargement of the patient’s internal organs.

The diagnosis of ATTR amyloidosis is suspected in persons with peripheral neuropathy or a family history of neuropathy and heart failure who are not found to have abnormal plasma cells when their bone marrow is tested. The diagnosis of ATTR or hereditary visceral amyloidosis is confirmed by molecular genetic testing.

Treatment and management

The treatment of the different types of amyloidosis varies considerably. Chemotherapy is the first line of treatment for AL amyloidosis. Patients are usually given melphalan (Alkeran) alone or in combination with dexamethasone. The goal is to eliminate the abnormal plasma cells in the bone marrow that produce the light chains that form the amyloid deposits. Another option is stem cell transplantation. Experimental treatments include two

medications developed to treat multiple myeloma: bortezomib (Velcade) and lenalidomide (Revlimid).

Treatment for AA amyloidosis requires treatment of the underlying inflammatory disease or condition. An investigational drug for this form of amyloidosis called Kiacta is presently undergoing clinical trials at Boston University's Amyloidosis Center.

The most effective treatment for ATTR is liver transplantation because the mutated transthyretin that forms the amyloid deposits is produced in the liver. An experimental drug that is being used to treat ATTR amyloidosis is tafamidis (Vyndaqel). The drug works by slowing the process of amyloid fibril formation.

Prognosis

The prognosis varies for different types of amyloidosis. Untreated AL amyloidosis has a very poor prognosis, with the median length of survival being about two years after diagnosis. Patients with severe heart disease related to AL amyloidosis have a life expectancy of only six months. The prognosis of AA amyloidosis depends on the type and severity of the underlying disease. Patients with ATTR amyloidosis have the best prognosis, living on average for ten years after diagnosis and liver transplantation.

Rebecca J. Frey, PhD

Amyotrophic lateral sclerosis

Definition

Amyotrophic lateral sclerosis (ALS) is a disease that breaks down tissues in the nervous system. It affects the nerves that are responsible for movement. ALS is also known as motor neuron disease. It is sometimes referred to as Lou Gehrig's disease, named after the baseball player whose career it ended.

Description

Amyotrophic lateral sclerosis is a progressive disease of the central nervous system. "A" means "no," "myo" implies muscle cells, and "trophic" refers to nourishment. The upper and lower motor neurons degenerate and die for unexplained reasons. The upper motor neurons are the nerve cells that extend from the brain to the spinal cord. The lower motor neurons are the nerve cells that extend from the spinal cord to the peripheral nerves. "Lateral" refers to the areas of the spinal cord that are affected, and "sclerosis" occurs as hard tissue replaces the previously originally healthy nerve.

The parts of the body that are not affected by ALS are not involved in the use of motor neurons. The mind remains very sharp and in control of sight, hearing, smell, touch, and taste. Bowel and bladder functions are generally not affected. Amyotrophic lateral sclerosis rarely

Degradation of motor neurons. Amyotrophic lateral sclerosis is the most common of the motor neuron diseases. Nerve degeneration and restricted production of the neurotransmitter dopamine result in deterioration of muscle tissue. This debilitating disease is characterized by rapidly progressive weakness, muscle atrophy and twitching, muscle spasticity, difficulty speaking (dysarthria), difficulty swallowing (dysphagia), and difficulty breathing (dyspnea). (Kateryna Kon/Science Source)

causes pain, yet it leaves patients dependent on the care of others during advanced stages.

ALS progresses rapidly, and paralyzed patients are usually under the intensive care of nursing facilities or loved ones, which can have a devastating psychological effect on the family members and the patient. In most cases, ALS is fatal within two to five years, although approximately 10% of those with the disorder live eight or more years.

Genetic profile

Most cases (90%) of ALS occur in people with no family history of the condition. These cases are most likely multi-factorial in cause, meaning that they are caused by primarily unknown environmental and genetic factors. Some suspected environmental causes are farming chemicals such as pesticides and insecticides, as well as mercury and manganese. An increase in ALS has been noted in Gulf War veterans as well.

Ten percent of cases of ALS are familial, although even in the same families there can be great variability in the type and severity of symptoms. Of those cases, most appear to follow an autosomal dominant pattern of inheritance, which means that an affected person has a 50% chance of passing the condition on to each child. Thirteen genes have been

identified in familial cases of ALS, although some are more common than the others. The *C9ORF72* gene is seen in 30 to 40% of familial cases. The *SOD1* gene is seen in 15 and the *FUS* and *TARDBP* genes are each seen in about 5% of familial cases.

A smaller number of cases are inherited in an autosomal recessive pattern, meaning that both parents of an affected person carry one mutated gene, which they both passed on to a child who then has two copies and is affected. Four genes have been identified in autosomal recessive cases. Some of these genes result in childhood onset of symptoms. There is also an X-linked form of ALS, which is most often carried by unaffected or mildly affected females on one of their two X chromosomes. This form of ALS can be passed on to their sons, who are then more severely affected because males have only one X chromosome. Only one gene has been identified in X-linked cases so far.

In 2021, scientists reported that the DNA of individuals with ALS in Malta, a small Mediterranean island with a relatively isolated genetic population, had no flaws in the genes that are known to contribute to a major number of ALS cases worldwide, but they *did* have flaws in other genes that caused their ALS symptoms.

There is some correlation between the genotype in familial cases and the phenotype or clinical symptoms. For instance, half of those with a mutation in the *SOD1* gene have symptoms by age 46. Half to 70% of those with mutations in the *FUS* gene have symptoms by age 51. As genetic technology is improving, a better understanding of the genetics of ALS may follow. Whole genome sequencing and whole exome sequencing are becoming more widely available and used.

Demographics

According to data from 2018, about, 2.6 per 100,000 people have ALS. About 5,600 people in the United States are newly diagnosed with ALS each year. The rate is slightly higher for women than for men. African Americans are less likely than Caucasians to have ALS, although this may be an artifact of reporting rather than

a true difference. Onset of ALS most commonly occurs between ages 40 and 60, but younger and older people may also develop ALS. Most often, ALS occurs in persons with no family history of ALS. With no family history, the average age of onset is 56 years. In cases where there is a family history, the average age of onset is 46 years.

Globally, ALS is considered one of the most common neuromuscular diseases. Finland has the highest rate of ALS in the world. An increased incidence of a condition that involves ALS and Parkinsonism has been reported in Guam.

Signs and symptoms

The cause of ALS is unknown. The reason why ALS strikes some people and not others is also unknown. Most likely, there are a number of different, yet biologically

Amyotrophic lateral sclerosis: pedigree analysis chart (Gale)

Spinal neuron comparison (Gale)

related, causes for ALS, possibly combined with environmental factors. The symptoms of ALS are caused by the death of motor neurons in the spinal cord and brain. Normally, these neurons convey electrical impulses from the brain to the muscles to stimulate movement in the arms, legs, trunk, neck, and head. As motor neurons die, their respective muscles cannot be moved as effectively. Muscle weakness results. In addition, lack of stimulation leads to muscle wasting or loss of bulk. Involvement of the upper motor neurons causes spasms, abnormal reflexes, and increased tone in the limbs. Involvement of the lower motor neurons causes persistent muscle wasting, twitching (fasciculations), and, eventually, paralysis.

The disease starts slowly, affecting just one limb, such as the hands or feet, and steadily progresses to more limbs and muscles. When muscles lack the nourishment they require, they begin to thin and deteriorate, which is the

hallmark of ALS. Muscle wasting is due to the inability of degenerating motor neurons to stimulate the muscles in a way that allows them to function and grow. Common examples of symptoms for ALS are muscle cramps and twitching, weakness in the hands, feet, or ankles, speech slurring, and swallowing difficulties. Other early symptoms include arm and leg stiffness, foot drop, weight loss, fatigue, and difficulty making facial expressions.

One of the earliest symptoms of ALS is weakness in the bulbar muscles. These muscles in the mouth and throat assist in chewing, swallowing, and speaking. Weakness of these muscle groups usually causes problems such as slurred speech, difficulty with conversation, and hoarseness of the voice.

As the disease progresses, the respiratory muscles (breathing muscles) weaken, resulting in increased difficulty

KEY TERM

Whole genome sequencing—Identifying the DNA code of a person's entire set of genes to look for mutations that may cause a disease or disorder.

with breathing, as well as coughing and possibly inhaling food or saliva. The potential for lung infection increases when food is inhaled into the lungs, which can cause death. Many patients find it more comfortable to use ventilators at that stage of the disease. Communication becomes very difficult. One way to accomplish feedback with others is to make use of the eyes. Blinking is one mode that patients with ALS can use to continue communication. About 5% of those with ALS develop a type of dementia in which they have cognitive deficits and personality changes. Some subtypes of ALS have been described primarily on the basis of symptoms involved in those cases.

As the disease progresses, victims gradually lose the use of their foot, hand, leg, and neck muscles, and paralysis results in affected muscle groups. They are able to speak and swallow only with great struggle. Sexual function is not affected. Breathing becomes increasingly difficult, and the patient may decide to prolong life with the use of assisted ventilation, which may decrease the risks of death from infections such as pneumonia. ALS is a complex and puzzling condition for a number of reasons, including clinical variability in symptoms, variability of age and site of onset, mixture of cognitive involvement, variable rate of progression, and mixture of those with a family history and those without. Furthermore, both upper and lower motor neurons are involved.

Diagnosis

ALS is difficult to diagnose. There is no single test for the disease. A second opinion is frequently recommended if ALS is suspected, since it is a fatal neurological disease. There is a set of diagnostic criteria for ALS called the Escorial Criteria, which suggest that in order to have a diagnosis of ALS, it must be clear that both upper and lower motor neurons are involved, the condition must be progressive, and there must be no evidence for the diagnosis of another similar condition. There are also classifications for the ALS diagnosis, such as definite, probable, possible, and suspected.

Examination

The diagnosis of ALS begins with a complete medical history and physical exam, plus neurological examinations to determine the distribution and extent of weakness.

The examinations are repeated at regular intervals to assess whether symptoms are getting progressively worse.

Tests

A series of diagnostic tests are performed to rule out other possible causes and diseases that resemble ALS, such as tumors of the skull base or high cervical spinal cord, thyroid disease, spinal arthritis, lead poisoning, or severe vitamin deficiency. Other possibilities to rule out include multiple sclerosis, spinal muscular atrophy, spinal bulbar muscular atrophy, spastic paraplegia, spinal cord neoplasm, polyarteritis, syringomyelia, myasthenia gravis, and muscular dystrophy. Electro-diagnostic tests such as electromyography (EMG) and nerve conduction velocity (NCV) are used to help diagnose ALS. Blood and urine tests, examination of spinal fluid, x-rays, and muscle and/or nerve biopsy are performed, as are imaging studies like magnetic resonance imaging (MRI), myelograms of the cervical spine, and CT (computed tomography) scans. ALS is rarely misdiagnosed following a careful review of all these tests.

Genetic testing for ALS is recommended when a person has a family history of the condition. Testing starts with the *SOD1* gene. If no mutations in that gene are identified, then other genes can be considered based on the clinical symptoms present. There are genetic tests for ALS that include gene panels, or a way to test several genes at once.

Treatment and management

As of 2021, there is no cure for ALS and no treatment that can significantly alter its course. Clinical trials for treating ALS including experimental drug treatments, and procedures are ongoing. Participation in a clinical trial is voluntary and normally at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>

Traditional

Emotional, psychological, and physical support are needed to ease the difficulty associated with this disorder. A team of medical specialists will be needed, including a neurologist, specialized nurses, pulmonologists, social workers, physical, speech and occupational therapists, and nutritionists.

Moderate activities are recommended in the early stages of the disease. Physical therapy can help muscles stay active and delay the resulting weakness. Eventually, walkers and wheelchairs will be needed. ALS patients are encouraged to maintain a healthy diet and to exercise

regularly for as long as possible. Education about ALS is very important in developing an understanding of the disease for family members as well as patients.

A physical therapist works with an affected person to implement exercise and stretching programs to maintain strength and range of motion. Swimming may be a good choice for people with ALS, as it provides a low-impact workout to most muscle groups. Regular stretching can prevent contracture (or muscle shortening), which is one result of chronic inactivity. Contracture limits a person's range of motion and is often painful. Several drugs are available to reduce cramping, a common complaint in ALS.

An occupational therapist can help design solutions to movement and coordination problems. This therapist can also provide advice on adaptive devices and home modifications.

Speech and swallowing difficulties can be minimized or delayed through training provided by a speech-language pathologist. This specialist can also provide advice on communication aids, including computer-assisted devices and simple word boards.

Nutritional advice can be provided by a nutritionist. A person with ALS often needs softer foods to prevent jaw exhaustion or choking. Later in the disease progression, nutrition may be provided by a gastrostomy tube inserted into the stomach.

Mechanical ventilation may be used when breathing becomes too difficult. Modern mechanical ventilators are small and portable, allowing a person with ALS to maintain the maximum level of function and mobility. Ventilation may be administered through a mouth or nose piece. It might also be administered through a tracheotomy tube, inserted through a small hole made in the windpipe. In addition to providing direct access to the airway, the tube decreases the risk of aspiration. While many people with rapidly progressing ALS choose not to use ventilators for lengthy periods, ventilators are increasingly being used to prolong life for a short time.

The progressive nature of ALS means that most persons with the disease will eventually require full-time nursing care, often provided by a spouse or other family member. While the skills involved are not difficult to learn, the physical and emotional burden of care can be overwhelming. Caregivers need to recognize and provide for their own needs, as well as those of people with ALS, to prevent depression, burnout, and bitterness.

Throughout the disorder, a support group can provide important psychological aid to the affected persons and their caregivers in coming to terms with the losses that ALS inflicts. Support groups are sponsored by both

- How can quality of life be improved?

the ALS Society and the Muscular Dystrophy Association.

Drugs

The drug riluzole (Rilutek, Tiglutik) is approved in both the United States and the European Union for treatment of ALS. Riluzole has been shown to delay the need for ventilator usage and to extend life by approximately one year. Otherwise, management aims to treat the symptoms that patients experience.

Alternative

Given the serious prognosis and absence of traditional medical treatments, it is not surprising that a large number of alternative treatments have been tried for ALS. Some studies have suggested that amino-acid therapies may provide some improvement for some people with ALS. While individual reports claim benefits for megavitamin therapy, herbal medicine, and removal of dental fillings, no evidence suggests that these offer any more than a brief psychological boost, often followed by a more severe let-down when it becomes apparent the disease has continued unabated. However, once the causes of this disorder are better understood, alternative therapies may be more intensively studied.

Prognosis

Amyotrophic lateral sclerosis normally progresses rapidly and leads to death from respiratory failure within three to five years. If the person involved is young, and the initial symptoms appear in the limbs, the disease tends to develop more slowly. About 10% of individuals with ALS live up to 10 years.

Androgen insensitivity syndrome

Definition

Androgen insensitivity syndrome is a genetic condition where affected people have male chromosomes and male gonads (testicles). The external genitals, however, have mild to complete feminization.

Description

Normal sexual development

In normal development, the chromosome sex determines the gonadal sex, which in turn determines the phenotypic sex. The chromosome sex is determined at conception; a male has the sex chromosome pair XY and a female has the chromosome pair XX. During the first 40 days of gestation, a male and female embryo appear the same and have undifferentiated gonads, which have the potential of becoming testes or ovaries. The presence of the Y chromosome in the male directs the undifferentiated gonads to become testicles. If no Y chromosome is present, such as in the female chromosome pair, the undifferentiated gonads become ovaries.

In males, the phenotypic sex, including the internal male structures and the external male genitalia, arises as a result of the hormones secreted from the testicles. The two main hormones secreted by the testicles are testosterone and mullerian duct inhibitor. Testosterone acts directly on the Wolffian duct, which give rise to the internal male structures including the epididymides, vasa deferentia, and seminal vesicles. Testosterone is converted into dihydrotestosterone, the hormone responsible for the development of the male urethra and prostate, and the external genitalia of the penis and the scrotum. The mullerian duct inhibitor is the hormone that suppresses the mullerian ducts and prevents the development of fallopian tubes, upper vagina, and uterus in males.

If no testicles are present, as with females, no mullerian duct inhibitor is formed and the mullerian ducts become the fallopian tubes, the upper vagina, and the uterus. The Wolffian ducts regress. Due to the lack of dihydrotestosterone, the external genitals are not masculinized and become female. Studies have shown that an ovary is not required for the formation of the internal female structures or the feminization of the genitals. If a testicle is not present, the development of the embryo will default to female development.

In most cases, the chromosomal sex, the gonadal sex, and the phenotypic sex are in agreement. Males have 46, XY chromosomes, testicles, and male internal structures and genitals. Females have 46, XX chromosomes, ovaries, and internal female structures and genitals.

Androgen insensitivity syndrome

Androgen insensitivity syndrome (AIS), also known as testicular feminization, is one of the most common conditions where the chromosome sex and gonadal sex do not agree with the phenotypic sex. Affected people have normal male chromosomes, 46, XY and testicles. The testicles secrete both testosterone and mullerian duct

Classification of AIS Phenotypes

Type	External genitalia (synonyms)	Findings
CAIS	Female ("testicular feminization")	Absent or rudimentary wolffian duct derivatives Inguinal or labial testes; short blind-ending vagina Little or no pubic and/or axillary hair
CAIS or PAIS	Predominantly female (incomplete AIS)	Inguinal or labial testes Labial fusion and enlarged clitoris Distinct urethral and vaginal openings or a urogenital sinus
PAIS	Ambiguous	Microphallus (<1 cm) with clitoris-like underdeveloped glans; labia majora-like bifid scrotum Descended or undescended testes Perineoscrotal hypospadias or urogenital sinus Excessive development of the male breasts during puberty
	Predominantly male	Simple (glandular or penile) or severe (perineal) "isolated" hypospadias with a normal-sized penis and descended testes or severe hypospadias with micropenis, bifid scrotum, and either descended or undescended testes Excessive development of the male breasts during puberty
MAIS	Male (undervirilized male syndrome)	Impaired sperm development and/or impaired masculinization Overdevelopment of the male breasts during puberty

Classification of AIS Phenotypes (Gale)

inhibitor as normal and no internal female structures form. However, due to defective androgen receptors, the Wolffian ducts and genitals cannot respond to the androgens testosterone and dihydrotestosterone. As a result, no male internal structures are formed from the Wolffian ducts and the external genitals are feminized.

The amount of feminization depends on the severity of the androgen receptor defect and is often characterized as complete androgen insensitivity (CAIS), partial androgen insensitivity (PAIS), and mild androgen insensitivity (MAIS). In complete androgen insensitivity, the alteration in the androgen receptor results in complete female external genitals. In partial androgen insensitivity, also called Reifenstein syndrome, partial androgen insensitivity results in female genitalia with some masculinization, ambiguous genitalia, or male genitalia with partial feminization. With mild androgen insensitivity, mild androgen resistance results in normal male genitalia or a male with mild feminization.

In both CAIS and PAIS, affected individuals are sterile (cannot have a child). In MAIS, the affected male may have fertility problems because of oligospermia (low sperm production) or azoospermia (no sperm production). In all types of AIS, secondary sex characteristics such as body and pubic hair can be abnormal. Mental impairment is not found in any of the types of androgen insensitivity syndromes, though poor visual-spatial ability has been observed. People with AIS can also be rather tall, though bone age is usually normal.

Genetic profile

Androgen insensitivity syndrome is a genetic condition that results from mutations (pathogenic variants) of the *AR*

gene, named for the androgen receptor. The androgen receptor is located on the long arm of the X chromosome (Xq11-q12). As women have two X chromosomes, they also have two androgen receptor genes. Men have only one X chromosome and a Y chromosome. Hence, they only have one copy of the androgen receptor gene.

When women have one copy of the androgen receptor altered, they are considered carriers of AIS. In most cases, the second, normal copy of the androgen receptor can compensate for the altered copy. However, in approximately 10% of women who are carriers for the altered androgen receptor gene, clinical signs such as sparse pubic and armpit hair or a delay to the start of their first menstrual period is observed.

46,XY conceptions that have alterations in the androgen receptor gene do not have a second copy to compensate for the altered copy. Hence, these people will have AIS. If the androgen receptor is severely altered, they will have CAIS. If not severely altered, they will have PAIS or MAIS.

All forms of AIS are inherited in an X-linked pattern. This means women who are carriers have a 25% chance of having an affected child. If a woman who carries one altered *AR* gene has a 46,XY conception, there is a 50% chance the child will have AIS. If a woman who carries one altered *AR* gene has a 46,XX conception, there will be a 50% chance the daughter will be a carrier.

When a person has AIS and has no other family history of the condition, approximately two-thirds of the time the affected person inherited the gene alteration from his mother. The other one-third of the time, the alteration of the androgen receptor was a new event (new mutation) in the affected person and was not inherited.

Cases of both gonadal mosaicism and somatic mosaicism have been reported with AIS. Gonadal mosaicism occurs when the alteration in the androgen receptor occurred not at conception, but in one of the gamete cells (sperm or egg). The rest of the cells of the body do not have the altered androgen receptor. With AIS, this can occur when one of a woman's early gamete cell has the new alteration in the androgen receptor but the rest of the cells in her body do not. All the eggs that come from the early gamete cell will also have the alteration. Her risk for having a child with AIS is increased. Somatic mosaicism occurs when the alteration in the androgen receptor occurs after conception but not in a gamete cell. Some of the person's cells will have the altered androgen receptor and other cells will not. The amount of cells with altered receptors and the location of those cells within the body will determine how severely affected a person will be.

A specific type of mutation, called a CAG repeat, within the androgen receptor gene is responsible for the neuromuscular condition spinobulbar muscular atrophy or Kennedy disease. See separate entry for more information.

Demographics

Complete androgen insensitivity syndrome occurs in approximately 1 in 64,000 46,XY births or 2-5 in 100,000 births overall. Partial AIS is at least as common as complete AIS. The incident of mild AIS is unknown, but is estimated to account for approximately 40% of male infertility due to severe oligospermia or azoospermia.

Signs and symptoms

Complete androgen insensitivity

Individuals with CAIS are born looking like normal female babies. Often, the condition is discovered in one of two ways. The child can have an inguinal hernia that upon repair is found to contain testicles. The most common presentation is during puberty with primary amenorrhea, or lack of the onset of the menstrual period. Affected individuals have a short, blind ending vagina and no uterus, cervix, fallopian tubes, or ovaries. During puberty, some girls will have absent or decreased pubic hair. Breasts develop normally and can be large in size with pale and immature nipples and areola. People with CAIS are usually raised as females and have normal female sexual orientation. All women with CAIS are sterile. In families with CAIS, all affected members will have complete androgen insensitivity and similar physical features.

KEY TERMS

Androgens—A group of steroid hormones that stimulate the development of male sex organs and male secondary sexual characteristics.

Chromosome—A microscopic thread-like structure found within each cell of the body and consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Mullerian ducts—Structures in the embryo that develop into the fallopian tubes, the uterus, the cervix and the upper vagina in females.

Wolffian ducts—Structures in the embryo that develop into epididymides, vasa deferentia, and seminal vesicles in males.

Partial androgen insensitivity syndrome

Children with PAIS usually present at birth due to ambiguous genitalia. The genitalia can look like female genitals with some masculinization, completely ambiguous genitals where the sex of the baby cannot be immediately determined or male genitals with some feminization. The degree of severity is a direct result of the severity of the genetic alteration in the androgen receptor and resulting amount of functional androgen receptor. The internal structures of PAIS are the same as CAIS, with absent fallopian tubes, cervix, uterus, and ovaries. Testes are present but do not produce sperm. Hence, people with PAIS are also sterile. People with PAIS also have primary amenorrhea, and breast development occurs in puberty. Unlike CAIS, affected individuals in the same family with presumably the same genetic alteration can have varying degrees of masculinization. As a result, some affected people may be raised as females, whereas others may be raised as males. Sex assignment is made based upon the structure of the genitals, the surgical correction needed, and the predicted response to androgens during puberty.

Mild androgen insensitivity

Males with mild androgen insensitivity usually have normal male genitals and internal male structures. During puberty, males with MAIS may have breast enlargement, sparse facial and body hair, and small penises. Some affected males may also have impaired sperm production resulting in oligospermia or azoospermia. As with CAIS, affected men within the same family usually have similar features.

Diagnosis

Diagnosis is usually made based upon clinical features, chromosome analysis, hormone levels, analysis of androgen receptor function in skin fibroblasts, and results of DNA testing of the AR gene. Clinical features are listed above for CAIS, PAIS, and MAIS. Chromosome analysis reveals normal male chromosomes. Affected individuals can have elevated luteinizing hormone, normal to slightly elevated testosterone, and high estradiol for men. Follicle stimulating hormone may also be normal to elevated. Reduced androgen receptor function in skin fibroblast cells is also used to aid in a diagnosis.

Direct genetic testing for molecular defects in the androgen receptor (AR) gene is available. DNA sequencing of the AR gene is the most productive form of DNA testing for detecting AR mutations (also known as pathogenic variants). DNA sequencing is the molecular determination of the precise sequence of nucleotides in a sample of DNA. By looking at the coding regions (exons) of the AR gene and the junctions between these coding regions, mutations or changes in the sequence of nucleotides can be found. The likelihood of finding a mutation (pathogenic variant) depends of the type of AIS the individual has:

- In individuals with CAIS, 65% to 95% of mutations in the AR gene will be found.
- In PAIS, DNA sequencing finds less than 50% of the AR mutations
- In individuals with MAIS, assessment of the accuracy of the testing is difficult to assess due to the suspected large number of undiagnosed cases.

If no mutations are detected by sequencing the AR gene, then deletion/duplication testing which looks for copy number variants is performed. Deletions or duplications in the AR gene are rare.

If DNA sequencing does not detect a mutation (pathogenic variant) in a person who clinically appears to have AIS, then other DNA testing techniques may be used. Multigene panels analyze groups of genes—the AR gene and other genes—that cause diseases that have symptoms similar to AIS disease simultaneously. However, while molecular DNA testing methods are very thorough, recent research has revealed that a significant percentage (perhaps as high as 40 percent) of individuals with clinical diagnosis consistent with AIS do not have detectable mutations in the AR gene. No other genes have been identified as contributing the phenotype of AIS. Research in this area is ongoing.

QUESTIONS TO ASK YOUR DOCTOR

- What surgical risks are associated with such procedures as breast reduction or testicle removal?
- What are the risks of hormone therapy?
- In CAIS, how long is estrogen therapy needed?
- How can I offer my child emotional support?

Treatment and management

Complete androgen insensitivity

Historically, treatment of CAIS often required the removal of the testicles from the pelvis or inguinal canal to decrease risk of testicular malignancy. Because the overall risk of malignancy is approximately 5% and rarely occurs before age 25, the testicles were usually removed after the development of the secondary sex characteristics, as the testes are needed for estrogen formation. After the removal of the testes, estrogen supplementation is started to aid in the development of secondary sex characteristics and to help prevent osteoporosis. Because the risk of malignancy is low, surgical removal of the gonads is becoming increasingly controversial. Surgery to lengthen the vagina may be necessary.

Partial androgen insensitivity syndrome

In individuals with ambiguous genitalia, the determination of the sex assignment during infancy is of primary importance. Health professionals and parents should make a decision as early as possible after a full multidisciplinary evaluation has been completed.

For those affected individuals raised as females, treatment is similar to CAIS except that removal of the testicles, if done, may be done earlier because it may cause enlargement of the clitoris during puberty. Reconstructive surgery of the genitals and lengthening of the vagina may be necessary.

People with PAIS raised as boys may need surgery to improve the appearance of the genitals. Androgen supplementation may be implemented, though long-term effects of androgen therapy are not known. Breast reduction surgery may be necessary after puberty.

Mild androgen insensitivity

Males with MAIS may require no treatment at all or breast reduction surgery after puberty. Males who are infertile may benefit from assisted reproductive technologies.

Prognosis

For CAIS and MAIS, the prognosis is excellent. Generally, gender assignment is not difficult and sexual orientation is female for CAIS and male for MAIS. Treatment usually involves minimal surgery and hormone supplementation. For individuals with PAIS, the prognosis is very dependent upon the severity of the condition. Assignment of gender can be difficult and should be done after an expert evaluation has been completed. Genital surgery can be more involved and some individuals with PAIS and other intersex conditions have encouraged the delay of assigning gender until the child is old enough to express a preference. This idea has not been readily embraced in the medical community of the United States but attitudes regarding gender are shifting.

It is important to provide information about the diagnosis of AIS to affected individuals in a caring, supportive environment that encourages questions and provides updated information. Support groups and psychological counseling can be beneficial as well.

Anencephaly

Definition

Anencephaly is a lethal birth defect characterized by the malformation of the brain and the absence of all or part of the skull and scalp. Anencephaly is a type of neural tube defect.

Description

Anencephaly is one of a group of malformations of the central nervous system collectively called neural tube defects. These birth defects occur very early in pregnancy, usually within the first four weeks and often before a woman knows she is pregnant.

Anencephaly is readily apparent at birth because of the absence of the skull and scalp and exposure of the underlying brain. The condition is also called acrania (absence of the skull) and acephaly (absence of the head). In its most severe form, the entire skull and scalp are missing. In some cases, termed "meroacrania" or "meroanencephaly," a portion of the skull may be present. In most instances, anencephaly occurs as an isolated birth defect with the other organs and tissues of the body forming correctly. In approximately 10% of cases, other malformations are present.

Risk factors

It is known that nutritional insufficiency, specifically folic acid insufficiency, is a predisposing environmental factor. Mutations of genes involved in folic acid metabolism are genetic risk factors. The recurrence risk of parents' having a second infant with a neural tube defect after the birth of an infant with anencephaly is 3%–5%. The recurrence may be anencephaly or another neural tube defect such as spina bifida.

Demographics

Anencephaly occurs in all races and ethnic groups. The prevalence rates range from less than one in 10,000 births (European countries) to more than ten per 10,000 births (Mexico, China). Factors involved in the difference of prevalence rates have not yet been determined.

Signs and symptoms

As an isolated defect, anencephaly appears to be caused by a combination of genetic factors and environmental influences that leads to the faulty formation of the nervous system. The specific genes and environmental conditions that contribute to this multifactorial causation are not completely understood.

A newborn affected by anencephaly is usually blind, deaf, unconscious, and unable to feel pain. In some cases, reflex action may be observed.

Diagnosis

Examination

Anencephaly is diagnosed by observation.

Tests

Prenatal diagnosis may be made by ultrasound examination after 12 to 14 weeks' gestation. Prenatal diagnosis of anencephaly can also be detected through maternal serum alpha-fetoprotein screening. The level of alpha-fetoprotein in the maternal blood is elevated because of the leakage of this fetal protein into the amniotic fluid.

Treatment and management

No treatment is indicated for anencephaly. Affected infants are stillborn or die within the first few days of life. The risk for occurrence or recurrence of anencephaly may be reduced by half or more by taking folic acid during the months immediately before and after conception. Natural folic acid, a B vitamin, may be found in many foods

QUESTIONS TO ASK YOUR DOCTOR

- What research is being done?
- Are you aware of any clinical trials?
- What can I do to decrease the risk of anencephaly occurring in future pregnancies?
- What supportive or comfort measures can I offer the baby?
- What genetic testing is recommended?
- Can you provide the name of a support group for parents who have had anencephalic babies?

(green leafy vegetables, legumes, orange juice, liver). Synthetic folic acid may be obtained in vitamin preparations and in certain fortified breakfast cereals. In the United States, all enriched cereal grain flours have been fortified with folic acid.

Prognosis

Anencephaly is uniformly fatal at birth or soon thereafter.

Diagram of Anencephaly

Infants born with anencephaly have either a severely underdeveloped brain or total brain absence. A portion of the brain stem usually protrudes through the skull, which also fails to develop properly. (Gale)

Angelman syndrome

Definition

Angelman syndrome (AS) is a genetic condition that causes severe intellectual disability, severe speech impairment, and a characteristic happy and excitable demeanor.

Description

Individuals with AS show evidence of delayed development by 6–12 months of age. Eventually, this delay is recognized as severe intellectual disability. Unlike some genetic conditions causing severe intellectual disability,

AS is not associated with developmental regression (loss of previously attained developmental milestones).

Severe speech impairment is a striking feature of AS. Speech is almost always limited to a few words or no words at all. However, receptive language skills (listening to and understanding the speech of others) and non-verbal communication are not as severely affected.

Individuals with AS have a balance disorder, causing unstable and jerky movements. This typically includes gait ataxia (a slow, unbalanced way of walking) and tremulous movements of the limbs.

AS is also associated with a unique “happy” behavior, which may be the best-known feature of the condition. This may include frequent laughter or smiling, often with no apparent stimulus. Children with AS often appear happy, excited, and active. They may also sometimes flap their hands repeatedly. Generally, they have a short attention span. These characteristic behaviors led to the original name of this condition, the “happy puppet” syndrome. However, this name is no longer used, as it is considered insensitive to AS individuals and their families.

Genetic profile

The genetics of AS are complex. There are at least five different genetic abnormalities that can cause the condition, all of which involve a specific region of the chromosome 15 inherited from the mother. This region is designated 15q11-13 (bands 11 through 13 on the long arm of chromosome 15). The fact that AS occurs only when there are abnormalities in this region of the maternal copy of chromosome 15 reflects a unique phenomenon known as imprinting. Imprinting is a chemical modification of DNA that acts as an “identification tag,” indicating which parent contributed the chromosome. Imprinted genes or chromosome regions are expressed or not expressed depending on which parent transmitted the chromosome. Abnormalities in the paternally (from the father) inherited 15q11-13 region cause a different genetic condition called Prader-Willi syndrome.

Chromosome deletion

The most common cause of AS is a small deletion (missing piece) in the maternally inherited chromosome 15. Specifically, the deletion occurs within 15q11-13. Approximately 70% of AS individuals have this deletion.

UBE3A mutation

In approximately 11% of AS cases, there is a mutation within the maternally inherited *UBE3A* gene. All the genetic mechanisms leading to AS appear to compromise expression of this gene, which is located

Angelman Syndrome

1. Etiology: Deletion, Uniparental Disomy or Unknown

2. Etiology: UBE3A mutation, Imprinting mutation or Unknown

Angelman syndrome: pedigree analysis chart (Gale)

within the 15q11-13 region. This gene is considered to be the “critical gene” responsible for AS, although its specific function is unknown.

Uniparental disomy

Some cases of AS result from inheritance of both chromosomes in the 15 pair from the father, an unusual genetic phenomenon known as uniparental disomy. In this circumstance, there is no chromosome 15 from the mother. Approximately 7% of AS cases result from this mechanism.

Imprinting defect

Approximately 3% of AS cases result from an imprinting defect on the maternally inherited chromosome 15. As noted above, imprinting is a chemical modification to the DNA that serves as a marker indicating the parent of origin and controls gene expression. If there is defective imprinting on the maternally inherited 15, then the genes in the 15q11-15q13 region may not be expressed, leading to AS.

Chromosome rearrangement

Rarely, AS may be caused by chromosomal breaks that occur in the maternally inherited 15q11-13 region. The breaks may occur as the result of a translocation (in which two chromosomes break and exchange material), an inversion (in which a piece of a chromosome breaks

and rejoins in the opposite orientation), or another disturbance of the chromosome structure involving the maternal 15q11-15q13. This mechanism is responsible for about 1% of AS cases.

Unknown mechanism(s)

In about 10%–15% of individuals with AS, no genetic cause can be identified. This may reflect misdiagnosis or the presence of additional, unrecognized mechanisms leading to AS.

Demographics

AS has been reported in individuals of diverse ethnic backgrounds. The incidence of the condition is estimated at 1 in 10,000 to 1 in 30,000.

Signs and symptoms

The first abnormalities noted in an infant with AS are often delays in motor milestones (those related to physical skills, such as sitting up or walking), muscular hypotonia (poor muscle tone), and speech impairment. Some infants seem unaccountably happy and may exhibit fits of laughter. By age 12 months, 50% of infants with AS have microcephaly (a small head size). Tremulous movements are often noted during the first year of life.

Seizures occur in 80% of children with AS, usually by three years of age. No major brain lesions are typically seen on cranial imaging studies.

The achievement of walking is delayed, usually occurring between two-and-a-half and six years of age. The child with AS typically exhibits a jerky, stiff gait, often with uplifted and bent arms. About 10% of individuals with AS do not walk. Additionally, children may have drooling, protrusion of the tongue, hyperactivity, and a short attention span.

Many children have a decreased need for sleep and abnormal sleep/wake cycles. This problem may emerge in infancy and persist throughout childhood. Upon awakening at night, children may become very active and destructive to bedroom surroundings.

The language impairment associated with AS is severe. Most children with AS fail to learn appropriate and consistent use of more than a few words. Receptive language skills are less severely affected. Older children and adults are able to communicate by using gestures or communication boards (special devices bearing visual symbols that correspond to commonly used expressions or words).

Some individuals with AS caused by a deletion of the 15q11-q13 chromosomal region may have a lighter skin complexion than would be expected given their family background.

Diagnosis

The clinical diagnosis of AS is made on the basis of physical examination and medical and developmental history. Confirmation requires specialized laboratory testing.

There is no single laboratory test that can identify all cases of AS. Several different tests may be performed to look for the various genetic causes of AS. When positive, these tests are considered diagnostic for AS.

DNA methylation studies

DNA methylation studies determine whether the normal imprinting pattern associated with the maternal (mother's) copy of the number 15 chromosome is present. The 15q11-q13 region is differently methylated (or "imprinted") depending on which parent contributed the chromosome. If an individual has a deletion of this region on the maternal chromosome 15, paternal uniparental disomy of the number 15 chromosomes (with no number 15 chromosome from the mother), or a defective imprinting mechanism, DNA methylation studies will be abnormal and indicate AS. This test detects the majority (approximately 78%) of cases of AS. Additional studies are then required to determine which of these three mechanisms led to AS development.

QUESTIONS TO ASK YOUR DOCTOR

- At what point do you recommend surgery rather than medication for gastric reflux?
- What will be the long-term benefit of speech therapy?
- What is the surgical risk for scoliosis repair?
- At what age should I take my child to an ophthalmologist (eye doctor)?

UBE3A mutation analysis

Direct DNA testing of the *UBE3A* gene is necessary to detect cases of AS caused by mutations in this gene. Cases of AS caused by *UBE3A* mutations usually have a normal imprinting pattern.

Fluorescent in situ hybridization (FISH)

FISH studies may be necessary to detect chromosome rearrangements that disrupt the 15q11-q13 region on the maternal copy of chromosome 15. The FISH method is a special way of checking for the presence, absence, or rearrangement of very small pieces of chromosomes. FISH testing can also readily detect AS caused by chromosome deletions, which account for approximately 70% of AS cases. FISH testing is often performed following an abnormal methylation study to determine whether a chromosome deletion accounts for the abnormal methylation pattern.

Treatment and management

There is no specific treatment for AS. A variety of symptomatic management strategies may be offered for hyperactivity, seizures, intellectual disability, speech impairment, and other medical problems.

The typical hyperactivity in AS may not respond to traditional behavior modification strategies. Children with AS may have a decreased need for sleep and a tendency to awaken during the night. Drug therapy may be prescribed to counteract hyperactivity or aid sleep. Most families make special accommodations for their child by providing a safe yet confining environment.

Seizures in AS are usually controllable with one or more anti-seizure medications. In some individuals with severe seizures, dietary manipulations may be tried in combination with medication.

Children with AS appear to benefit from targeted educational training. Physical and occupational therapy may improve the disordered, unbalanced movements typical of AS. Children with a severe balance disorder may require special supportive chairs. Speech therapy is often directed towards the development of nonverbal communication strategies, such as picture cards, communication boards, or basic signing gestures.

Individuals with AS may be more likely to develop particular medical problems, which are treated accordingly. Newborn babies may have difficulty feeding, and special bottle nipples or other interventions may be necessary. Gastroesophageal reflux (heartburn) may lead to vomiting or poor weight gain and may be treated with drugs or surgery. Constipation is a frequent problem and is treated with laxative medications. Many individuals with AS have strabismus (crossed eyes), which may require surgical correction. Orthopedic problems, such as tightening of tendons or scoliosis, are common. These problems may be treated with physical therapy, bracing, or surgery.

Prognosis

Individuals with AS have significant intellectual disability and speech impairment that are considered to occur in all cases. However, they do have the capacity to learn and should receive appropriate educational training.

Young people with AS typically have good physical health aside from seizures. Although lifespan data are not available, the lifespan of people with AS is expected to be normal.

Ankylosing spondylitis

Definition

Ankylosing spondylitis (AS) is a relatively common disease that causes inflammation of the area where ligaments and tendons insert into the bone. The inflammatory process eventually leads to reduced mobility or immobility of affected joints. Specific joints are characteristically involved, notably in the spine and pelvis.

Description

Ankylosing spondylitis belongs to a group of disorders called the seronegative spondyloarthropathies. Each disease in this group is characterized by arthritis affecting the spine, as well as the absence of rheumatoid factor, a diagnostic marker that is present in rheumatoid arthritis and helps distinguish it from the group of diseases that includes AS. AS affects primarily the spine and the sacroiliac joint where the spine meets the hips. Progressive symptoms eventually result in fusion of these joints, pain, and markedly decreased joint mobility. AS is considered an autoimmune disease, meaning that symptoms are the result of the action of the immune system of the body against its own tissues. Although the exact mode of action is unknown, there is a strong association between AS and a specific type of human leukocyte antigen, HLA-B27. HLA are genetically determined proteins that play an important role in the functioning of the immune response of the body, in that they enable the immune system to distinguish between its own cells and foreign cells. Therefore, HLA type is important in immunity as well as organ and tissue transplantation.

Genetic profile

AS is considered a multifactorial disorder, or one that is the result of an interaction between genetic and environmental factors. Two genes have been identified that confer susceptibility to AS, both of which are forms of an HLA gene on chromosome 6. Some HLA types have been implicated in various autoimmune diseases, or diseases in which the immune system attacks the body's own cells and tissues.

An X-ray image of a spine showing ankylosing spondylitis.
(Suttha Burawonk/Shutterstock)

The association of HLA B-27 and AS has been clearly established. Ninety to 95% of individuals with AS are B-27 positive, and since AS appears to be a dominant trait, the presence of at least one B-27 allele (a form of the gene) confers a greatly increased chance of developing symptoms. While this population risk may seem relatively high, it is important to realize that only about 9% of the population carries the B-27 allele. Of these individuals who are B-27 positive, only 2%–8% will develop AS.

Other environmental and genetic factors most certainly contribute to development of the disease. This becomes more evident when considering that B-27 positive individuals with an affected first-degree relative have a significantly higher chance of developing AS than a B-27 positive individual with no family history. In

families with multiple affected members, studies estimate that no more than half of AS recurrence is explained by HLA type. Additionally, there are several B-27 subtypes that have been studied; some confer susceptibility and some do not. Importantly, about 5% of people with AS are B-27 negative. Other environmental and/or genetic factors must certainly be associated with disease in these individuals. Another HLA type—B-60—has also been shown to confer susceptibility, although the association appears to be much weaker and is not seen in all studies. Certain infections are suspected of being necessary for triggering AS in some individuals. In the future, additional susceptibility genes and environmental factors can be expected to be identified.

Demographics

Approximately 0.25% to 1.5% of the population is affected with AS. Prevalence of the disease is comparable to the frequency of the HLA B-27 allele in the population, which varies among ethnic groups. Native North Americans, Alaskan Eskimos, and Norwegian Lapps all have relatively high levels of B-27 and AS. Low levels of B-27 and AS occur among individuals of most types of African ancestry, Australian aborigines, and Native South Americans. Generally, for every affected female, there are two to three affected males.

Signs and symptoms

The signs of AS vary, but a typical case involves progressive lower back pain and morning stiffness. The immune response at the point where the ligaments or tendons insert into the bones initially causes bone inflammation and fragility, followed by fibrosis, or the formation of fiber tissue. The area reacts by forming new bone, which eventually fuses, limiting motion. AS can also affect peripheral joints in a manner similar to other types of arthritis. The vertebral joints of everyone with AS are affected, and 50% of people will also have significant hip arthritis. Osteoporosis in advanced AS commonly results in fractures of the spine.

AS also affects areas other than the bones and joints. An eye complication called *anterior uveitis*, which is easily treated and generally does not affect vision, develops in 40% of people with AS. Rarely, the disease may affect the heart or aorta. Kidney failure is a rare complication. Lung function can be affected because of bone changes that affect the mechanics of breathing. Therefore, individuals with AS should refrain from smoking to avoid early respiratory failure. Ninety percent of affected individuals experience the first symptoms before age 45. Males are more commonly affected than females, who tend to be diagnosed later partly because of milder symptoms.

KEY TERMS

Ankylosis—Immobility of a joint due to the formation of new bone at the site of inflammation.

Cervicitis—Inflammation of the cervix.

Enthesitis—Inflammation at the place where the ligaments insert into the bone.

Enthesopathy—Disorder of the ligament attachment to the bone.

HLA-B27—Stands for a specific form of human leukocyte antigen, the proteins involved in immune system function. Strongly associated with ankylosing spondylitis.

Human leukocyte antigens (HLA)—Proteins that help the immune system function, in part by helping it to distinguish “self” from “non-self.”

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Osteoporosis—Loss of bone density that can increase the risk of fractures.

Psoriasis—A common, chronic, scaly skin disease.

Rheumatoid arthritis—Chronic, autoimmune disease marked by inflammation of the membranes surrounding joints.

Rheumatoid factor—Antibodies present in the majority of individuals with rheumatoid arthritis. A

diagnostic marker for rheumatoid arthritis that is absent from ankylosing spondylitis and other seronegative spondyloarthropathies.

Sacroiliac joint—The joint between the triangular bone below the spine (sacrum) and the hip bone (ilium).

Sacroiliitis—Inflammation of the sacroiliac joint.

Sensitivity—The proportion of people with a disease who are correctly diagnosed (test positive based on diagnostic criteria). The higher the sensitivity of a test or diagnostic criteria, the lower the rate of “false negatives,” people who have a disease but are not identified through the test.

Specificity—The proportion of people without a disease who are correctly classified as healthy or not having the disease (test negative based on diagnostic criteria). The higher the specificity of a test or diagnostic criteria, the lower the number of “false positives,” people who don’t have a disease but who “test” positive.

Spondyloarthritis (spondylitis)—Inflammatory disease of the joints of the spine.

Urethritis—Inflammation of the urethra.

Uveitis—Inflammation of all or part of the uvea, which consists of the middle vascular portion of the eye, including the iris, ciliary body, and choroid.

Diagnosis

Diagnostic criteria that were established by the European Spondyloarthropathy Study Group in the early 1990s are still used today. A clinical diagnosis of AS requires the presence of spinal pain caused by inflammation or inflammation of the membrane surrounding the joints, which can be either asymmetric or involving primarily the lower limbs. One or more of the following conditions must also be present:

- family history of AS
- sacroiliitis (inflammation of the sacroiliac joint) demonstrated by x-ray
- acute diarrhea within one month before the appearance of symptoms
- inflammatory bowel disease
- psoriasis (a scaly skin disease)
- urethritis (inflammation of the urethra)
- cervicitis (inflammation of the cervix)

- alternating buttock pain
- enthesopathy (disorder of the ligament attachment to the bone)

This diagnostic description has close to an 87% sensitivity, meaning that 87% of those with AS are picked up using this description. Conversely, 13% of those with AS will not be identified as having the disease based on this description. The description has a specificity that is also approximately 87%, meaning that 87% of the time, a person classified as having AS actually has AS, as opposed to another disease or no disease. Conversely, about 13% of the time, this description will incorrectly classify someone who actually has a different disease as having AS.

This is a challenging diagnosis to make correctly. Testing for HLA B-27 can improve diagnosis by confirming specificity. In other words, when it looks like someone has AS based on the above description of conditions, a positive B-27 test will make the physician

QUESTIONS TO ASK YOUR DOCTOR

- At what point should physical therapy be initiated?
- What are the risks and benefits of surgery?
- What are the risks and benefits of long-term use of nonsteroidal anti-inflammatory medications?
- How often should I have eye exams?

more certain that person is a true positive for AS. As imaging of the sacroiliac joint improves through the use of a technology called magnetic resonance imaging (MRI), diagnosis of AS may also improve. However, diagnosing a person with AS prior to the development of signs seen on x-ray or MRI will continue to be very difficult.

Treatment and management

Physical therapy plays a major role in maintaining flexibility, range of motion, posture, and, ultimately, mobility. Surgery can improve joint function, as well as minimize associated pain, which may be treated with nonsteroidal anti-inflammatory medications. Other medications—sulfasalazine and methotrexate—can provide some relief for peripheral arthritis. Cycloplegics (medications that paralyze the ciliary muscle of the eye) and local steroids are effective at treating anterior uveitis. Rare complications are treated depending on their symptoms. Avoidance of smoking is encouraged to maintain lung function.

Prognosis

For most affected individuals, treatment and management is successful at maintaining quality of life. Quality can be significantly impacted, however, for the occasional individual with a severe, progressive course of the disease. Vision can be affected in some individuals with anterior uveitis that is not responsive to treatment, but this is rare. The rare complication of kidney failure can limit life expectancy, as can respiratory failure that may result from smoking.

Apert syndrome

Definition

Apert syndrome is a rare genetic disorder that causes certain skull bones to close, or fuse, too soon in development. The premature closure leads to a distorted face with an unusually tall skull. Children with Apert syndrome also have fused fingers and toes, known as syndactyly. Another name for this disorder is acrocephalysyndactyly.

Description

A French physician named E. Apert first reported in 1906 the syndrome that bears his name. He detailed the skull malformation, midface hypoplasia (underdevelopment) and the hand abnormalities. The hand of a person born with Apert syndrome appears mitten-shaped because of the finger fusion. The child can have normal intellectual ability or severe intellectual disability.

Webbing of the toes is a characteristic sign of Apert syndrome. (M.A. Ansary/Science Source)

Apert syndrome also is known as FGFR-related craniosynostosis, and is one of eight known disorders in the group. FGFR refers to the fibroblast growth factor receptor (FGFR) gene responsible for the disorder, and craniosynostosis describes the premature skull fusion.

Genetic profile

Apert syndrome (AS) is an autosomal dominant disorder, meaning that a person only has to inherit one non-working copy of the gene for the condition to occur. In most cases, AS is sporadic, meaning that the parents are usually unaffected, but a fresh mutation or gene change occurring in the egg or sperm is passed to the affected child. For these families, the chance to have another affected child is very low. An affected parent has a 50% chance of passing on the abnormal gene to their child, who will then also have Apert syndrome.

Two unique mutations in the FGFR2 gene located on chromosome 10 were discovered in 1995. This gene directs the development of bone formation. At least seven mutations of the FGFR2 gene have been identified that cause Apert syndrome. Most mutations are influenced by either of two more common mutations found in people with the syndrome.

After comparing the physical findings with gene mutations causing AS, researchers noted that one mutation was associated with facial disorder. The other mutation produced a more severe form of syndactyly. With the facial mutation, corrective surgery can lead to much more improved facial appearance.

Demographics

Apert syndrome has been estimated to occur in 1 of every 60,000-160,000 births. All races and both sexes are equally affected.

Signs and symptoms

At birth the craniofacial (pertaining to the skull and face) appearance is striking. Early or premature closure of the skull sutures (layer of fibrous tissue connecting the skull bones) makes the skull grow taller than normal with a short distance from the front to the back of the head. The coronal suture that connects the frontal and parietal bones fuses early in infants with Apert syndrome. The buildup of pressure on the brain is minimal because the fontanelles, or soft spots, and midline of the skull remain open. Because the space within the eye sockets is small, the eyeballs bulge outward and to the side. The child's eyelids also have a downward slant and cannot completely close.

From the middle of the eye sockets to the upper jaw, the affected child's face is sunken in or concave when viewed from the profile. This midfacial hypoplasia causes the upper jaw to slope backward, pushing the lower teeth in front of the back teeth.

The child's mouth area has a prominent mandible (lower jaw), down-turned corners, a high arched palate, cleft palate (an opening in the roof of the mouth), crowded upper teeth, poor contact between the upper and lower teeth, and delayed tooth eruption.

Syndactyly of the fingers and toes involves not only soft tissues but also the bones, nerves, and tendons. The child usually cannot flex the fingers and toes after the first digit. The thumb can be unattached or fused to the other fingers. Also, the other fingers may or may not be fused to each other in varying degrees. Fusion of the toes is less worrisome. Correction only becomes necessary when walking is difficult.

Most children with AS are noisy breathers. The nose and airways leading to the lungs are smaller than usual. These narrow passageways probably make breathing more difficult. If breathing is more troublesome at night, sleep apnea can occur. This stoppage of breathing while sleeping deprives the brain and body of oxygen. The child may experience mental impairment as a result of oxygen deprivation.

Excessive sweating is often seen in people with AS. Researchers do not know why the sweat glands are overactive. As the children reach puberty, they develop excessive acne. A skin specialist or dermatologist can help to control it.

The height and weight of children with AS is usually normal. However, their learning ability can be affected. A small number of children with Apert syndrome have a normal level of intelligence, but most have some degree of intellectual disability. Studies have shown that the IQs of children with AS tend to be lower than normal.

Apert syndrome: pedigree analysis chart (Gale)

Diagnosis

During the newborn period, most babies are diagnosed after a geneticist examines them. This doctor specializes in diagnosing and explaining hereditary conditions. The unusual facial features and hand syndactyly are unique to AS. Testing for the mutations known to cause AS should be arranged to make a diagnosis. When a mutation is not found, the physical findings alone can support the diagnosis.

Occasionally during an ultrasound examination, a fetus shows characteristics suggesting AS. This examination is best done after 16 weeks of pregnancy. Ultrasound is the use of high-frequency sound waves to create a real-time image of the fetus. Unlike x-rays, ultrasound uses no radiation and the fetus can be examined for size, viability, and birth defects.

An experienced physician or ultrasound technologist performing the examination may detect the caved-in profile and syndactyly. More than one examination may be necessary to confirm the findings. If AS is suspected, genetic testing can be offered during the pregnancy. The pregnant woman can undergo an amniocentesis to obtain fetal cells that can be analyzed for the mutations causing

AS. Amniocentesis is the removal of the amniotic fluid surrounding the fetus by inserting a needle through the uterus. Results may take as long as four weeks.

Treatment and management

The best treatment for AS begins at birth with the correct diagnosis. To provide better care, a craniofacial team should be involved. With the team approach all the specialists are in one center to minimize the number of appointments and corrective surgeries. More important, this team consists of specialists who understand the complex problems of AS and the family's concerns. Included on this team are a craniofacial surgeon, neurosurgeon, otolaryngologist (specialist of the ears, nose, and throat), ophthalmologist (eye specialist), orthodontist, speech therapist, and psychologist. A pediatric nurse, geneticist or genetic counselor, and social worker may also be part of the team during the first few years of the child's life. Many major medical centers will have a craniofacial team, or the family can be referred to one.

Working together, the craniofacial surgeon and neurosurgeon perform the multiple surgeries to reshape the tower skull. They reopen the prematurely closed sutures

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that causes improper connection of the nasal passages and the mouth.

Craniofacial—Relating to or involving both the head and the face.

Dermatologist—A physician who specializes in disorders of the skin.

Fontanelle—One of several “soft spots” on the skull where the developing bones of the skull have yet to fuse.

Hypoplasia—Incomplete or underdevelopment of a tissue or organ.

Mandible—Lower jaw bone.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an

individual, or manifest as disease, and can be transmitted to offspring.

Ophthalmologist—A physician specializing in the medical and surgical treatment of eye disorders.

Orthodontist—A dentist who specializes in the correction of misaligned teeth.

Otolaryngologist—A physician who specializes in the care of the ear, nose, and throat and their associated structures.

Psychologist—An individual who specializes in the science of the mind.

Sleep apnea—Temporary cessation of breathing while sleeping.

Speech therapist—A professional who specializes in teaching simple exercises to improve speech.

Suture—A seam that joins two surfaces together.

Syndactyly—Webbing or fusion between the fingers or toes.

Ultrasound—An imaging technique that uses high-frequency sound waves to help display internal structures in the body.

between the skull bones and then pull the front of the skull forward to create space within it and enlarge the eye orbits. Average age of patients for these operations is about 4–8 months.

From ages five to nine, the child often has a surgical procedure called a midface advancement. This technique corrects the concave profile that becomes pronounced because the child's upper and lower face grow normally while the middle of the face grows slowly. Corrective facial surgeries continue until the early adult years when growth is finally completed.

The neurosurgeon may perform the operations to unfuse and straighten the fingers. However, a completely normal hand cannot be created.

Frequent ear infections can decrease a child's hearing level. The otolaryngologist can monitor the hearing. Sometimes tiny plastic tubes are placed in the ears to prevent hearing loss from repeated infections.

The abnormal placement of the eyes and its muscles can sometimes prevent a child from looking straight ahead with both eyes. An ophthalmologist should examine the eyes regularly and correct a muscle imbalance of the eyes with surgery.

An orthodontist (dentist who specializes in correcting misaligned teeth) monitors the teeth because the abnormal jaw structure causes poor development and placement. An oral surgeon may correct the misalignment of the teeth. Proper positioning of the teeth improves speech and facial appearance.

Speech and language delay can result from decreased hearing and an unusual jaw shape. A speech therapist works with the child to develop language skills through simple exercises.

The facial appearance of Apert syndrome can have a devastating emotional effect on the child and family. Support from a psychologist (a specialist in science of the mind) can help the child develop a positive self-image and help parents cope with feelings of guilt. Often parents will blame themselves for a child's condition even when they in no way caused it or could have prevented it. The multiple doctors' visits and surgeries can create undue stress as well.

During the many hospitalizations, a pediatric nurse will care for the child. This nurse has received specialized training in the treatment of children with craniofacial disorders. Also, the nurse may introduce the child to the hospital.

QUESTIONS TO ASK YOUR DOCTOR

- What are the risks of surgery during infancy?
- What is the risk of my child having mental deficiencies?
- Do you recommend occupational or physical therapy, and at what age should these therapies begin?
- What measures can we implement at home to improve the prognosis?

Diagnosis of Apert syndrome will usually be made by the geneticist. The family will discuss with the genetic counselor how AS is inherited and the chance for future children to be affected.

Having a child with AS can place a tremendous financial strain on the family. A social worker gives the family important information about medical coverage. This person can also help coordinate medical care and special-needs education.

Prognosis

Many factors affect the prognosis of a child with AS. The age at which the first surgery takes place to create spaces between the skull bones is important. Intellectual disability can result from the buildup of pressure on the brain. Having a supportive, loving family environment increases the chances for normal development. Children with complex medical problems who lack a supportive setting often have delayed mental, social, and emotional development.

Although the hands will never be completely normal, surgeries to separate and straighten the fingers can be done. Tasks such as writing and manipulating buttons can be difficult. Adaptive devices in school and home will allow for more independence. Separation of the toes usually does not improve walking but may improve the child's self-image.

Persons with AS who have a normal intelligence level can have full, productive lives. Vocational training will help those with borderline intelligence.

Arginase deficiency

Definition

Arginase deficiency is an inborn error of metabolism that results from a defect in the urea cycle. This cycle is a series of biochemical reactions that occur in the body in order to remove ammonia from the bloodstream.

Description

Arginase deficiency is also known as ARG deficiency, argininemia, or hyperargininemia. The disorder belongs to a group of conditions known as urea cycle disorders. During normal cellular function, proteins are broken down into nitrogen waste products and put into the blood stream as ammonia. The urea cycle transforms this toxin into urea, which can be safely removed by the kidneys as urine. Lack of an enzyme from the urea cycle, such as arginase, can result in the buildup of toxins in the body. There are eight diseases that belong in the

KEY TERMS

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Urea cycle disorder—A disease caused by a lack of an enzyme that cleans the blood of ammonia.

group of urea cycle disorders. Arginase deficiency is thought to be one of the rarest of these disorders.

The enzyme arginase is the last step of the urea cycle, where it turns arginine into ornithine and urea. If a person is born with arginase deficiency, he or she will build up arginine in the blood. Since earlier steps in the urea cycle are left intact, patients may or may not build up ammonia in the blood. If not treated, children can develop muscle problems and developmental delays.

Genetic profile

Arginase deficiency is inherited in an autosomal recessive fashion and linked to mutations in the *ARG1* gene. Thus, both parents of an affected child are typically found to be carriers of a mutation in *ARG1*. The chance of having an additional child with arginase deficiency is 25%.

Demographics

Like other autosomal recessive diseases, arginase deficiency remains rare. The first signs of this disease tend to occur while the patient is still very young. A child may have a normal birth, infancy, and may not show any signs of the disease for quite a few years. There is no racial difference. Furthermore, men and women are both as likely to have the disease.

Arginase deficiency, along with N-acetylglutamate synthetase deficiency, is considered to be the least common of the urea cycle defects. Its incidence has been estimated at between one in 350,000 and fewer than one in 1,000,000, but the true incidence in non-related populations is unknown. Arginase deficiency may be more common in parts of Japan and among French Canadians.

Signs and symptoms

The onset of this disease tends to be subtle. While the first symptoms of this disease show up while the patient is still a baby, some infants are said to be normal before beginning to have the symptoms. In many cases, the disease is not found at first. When the initial symptoms

manifest themselves, the child is diagnosed with “cerebral palsy” (a general term for neurologic problems that result in altered development—often starting at birth). The symptoms include: missing developmental milestones, poor feeding, fussy behavior, lower alertness, spasticity of lower limbs, poor coordination, tremors, seizures, and mental disability. Other symptoms include choreoathetotic movements (strange, uncontrollable writhing movements of limbs). Additionally, for affected patients, a high-protein meal makes symptoms worse. Affected children may also have an enlarged liver from the buildup of toxins.

Diagnosis

In the United States, most affected individuals will be identified by newborn screening at birth and before the onset of symptoms. However, in the absence of newborn screening, diagnosis is made after children are observed with symptoms. The illness should be considered for children who have both a developmental delay and stiffness of the ankles and legs that interfere with walking. It should also be included anytime that other urea cycle disorders are considered. A diagnosis is made when an individual is either found to have biallelic mutations in *ARG1* or reduced red blood cell arginase enzyme activity. Almost all individuals with arginase deficiency have no detectable arginase enzyme activity in red blood cells. In other urea cycle disorders, patients tend to have hyperammonemia (a high amount of ammonia in the blood), but in arginase deficiency the ammonia levels are rarely raised.

If patients have one child with this disease, they can be counseled about the risk of disease in future children. Since this disease is inherited in an autosomal recessive pattern, each time carrier parents have a child there is a 25% chance that they will have an affected child. Prenatal diagnosis for at-risk pregnancies is possible by analysis of DNA extracted from fetal cells obtained by amniocentesis usually performed at approximately 15–18 weeks’ gestation. However, both disease-causing alleles of an affected family member must be identified in the family before prenatal testing can be performed. If molecular genetic testing is not possible, prenatal diagnosis for pregnancies at 25% risk may be possible by measuring arginase enzyme activity in fetal red blood cells obtained by percutaneous umbilical blood sampling after 18 weeks’ gestation.

Treatment and management

Treatment of arginase deficiency is similar to treatment methods for other urea cycle disorders. One would want to decrease, as much as possible, the amount of

QUESTIONS TO ASK YOUR DOCTOR

- What signs or symptoms indicate that our child may have arginase deficiency?
- Are tests available to confirm a diagnosis of arginase deficiency?
- What do the diagnostic tests for arginase deficiency involve?
- What kinds of treatment or other medical care is available for a child with arginase deficiency?

arginine that is building up. This is done through control of protein intake in foods. Arginine is one of the twenty amino acids that make up proteins, and if its intake is stopped, then the amount that can build up in a patient will be lessened. Supplements of essential amino acids (amino acids that cannot be made by the body and must be obtained through food) are given so that children do not become ill from malnourishment. Medications may be used that help block ammonia production. These medications are typically administered intravenously, but sometimes orally.

Other symptoms can also be controlled. For example, patients who have seizures should be treated with an anti-seizure medication. Also, physical therapy can be helpful for patients with stiff legs and walking problems.

Carrier testing for at-risk family members using red blood cell arginase activity detects most carriers. Carrier testing for at-risk family members is available once the mutations have been identified in the family line.

Prognosis

The long-term effects of arginase deficiency are better than that for other urea cycle disorders. With proper food intake and medical management, children can have much milder symptoms. Prior to newborn screening, the disease was often not found until after severe problems occurred. Data about patients that live until they are adults is limited, but many cases of patients living through teenage years have been reported. Hence, prognosis is clearly related to how early the disease can be found.

Arnold-Chiari malformation

Definition

Arnold-Chiari malformation is an abnormality in the lower portion of the skull and either the cerebellum or the brain stem. There are several different types of Arnold-Chiari malformations, which may be caused by rare genetic abnormalities.

Description

In 1891, Austrian pathologist Hans Chiari first described what have become known as Arnold-Chiari malformations types I, II, and III. The German pathologist Julius Arnold expanded the definition of type II.

Arnold-Chiari malformation: brain comparison (Gale)

The term “Arnold-Chiari malformation” is now used to define all four types. Arnold-Chiari malformation is also called Arnold-Chiari syndrome or Chiari malformation.

The cerebellum and brain stem are located in the posterior fossa, an area at the base of the skull attached to the spinal cord. In an Arnold-Chiari malformation, the posterior fossa does not form properly. Because the posterior fossa is small, the brain stem, cerebellum, or cerebellar tonsils are squeezed downward through an opening at the bottom of the skull. The cerebellum, brain stem, or both may extend beyond the skull or protrude into the spinal column. Therefore, Arnold-Chiari malformations are also known as congenital tonsillar herniation, tonsillar ectopia, or tonsillar descent. The displaced tissues may obstruct the flow of cerebrospinal fluid (CSF), the fluid that flows through and around the brain and spinal cord to nourish and protect them. Obstructed CSF flow can cause various symptoms, including dizziness, muscle weakness, numbness, vision problems, headache, and problems with balance and coordination.

Although the malformation is almost always present at birth (congenital), symptoms may not develop until later in life. Some mild forms never cause symptoms and those affected are unaware that they have the condition. However, there is much variety in symptoms and severity of Arnold-Chiari malformation.

Types

Arnold-Chiari malformations are classified according to their severity and the portion of the brain that protrudes into the spinal column.

- Type 0—in which there is little or no descent of the cerebellar tonsils—may still produce symptoms because of abnormalities in the flow of the CSF.
- Type I, in which the base of the skull and upper spine do not form properly, is the most common and least severe malformation. Symptoms may arise during adolescence or adulthood, or there may be no symptoms, and the malformation is only discovered during examination for another condition.
- Type II is more severe. The back of the brain protrudes through the bottom of the skull. It is almost always associated with a form of spina bifida, in which the spinal canal and backbone do not close before birth. A sac called a myelomeningocele protrudes through the abnormal opening in the spinal column and may contain part of the spinal cord, spinal membranes, or CSF. Type II is diagnosed in childhood and can cause partial or complete paralysis of the body below the opening in the spinal column.
- Types III and IV are very rare and cause severe neurological defects. In type III, the back of the brain protrudes through an opening in the back of the skull.

With Type IV, the back of the brain fails to develop properly.

Arnold-Chiari malformations can be associated with other conditions in addition to spina bifida. These can include excessive fluid in the brain (hydrocephalus), a fluid-filled cyst in the spinal cord (syringomyelia), or spinal curvature.

Genetic profile

The causes of Arnold-Chiari malformations are unknown. The malformation almost always occurs during fetal development. It has been hypothesized that the cerebellum is forced downward because the base of the skull is too small or that there is overgrowth in the cerebellar region that pushes the cerebellum downward into the spinal canal. In some cases there appears to be a genetic component, with the abnormality affecting multiple family members. However, no genes responsible for the malformation have yet been identified. It is also possible that Arnold-Chiari malformations are caused by exposure to harmful substances during prenatal development.

Demographics

In the past, Arnold-Chiari malformation was estimated to occur in about 1 in every 1,000 births. However, the increased use of diagnostic imaging has suggested that it may be much more common. Its incidence appears to be higher in females than in males. Type II appears to be more prevalent in certain groups, including people of Celtic descent.

Signs and symptoms

Symptoms of Arnold-Chiari malformations vary greatly. Some people with type I malformations never develop symptoms. More often, symptoms appear in the third or fourth decade of life. Most symptoms arise from pressure on the cranial nerves or brain stem. They may be vague or resemble symptoms of other medical problems, delaying diagnosis. Headache is one of the most common symptoms. The headache generally begins in the neck or base of the skull and may radiate through the back of the head. Coughing, sneezing, or bending forward may bring on these headaches, which can last minutes or hours and may have associated nausea.

When Arnold-Chiari malformation occurs in association with other congenital defects, diagnosis may be made shortly after birth. In infants, symptoms are caused by pressure on the lower portion of the brain and the brain stem. These symptoms may include:

- vomiting
- chronic cough or hoarseness

KEY TERMS

Brain stem—The lower part of the brain that connects to the spinal cord.

Cerebellar tonsils—Lobes on the undersurface of each hemisphere of the cerebellum.

Cerebellum—The part of the brain between the brain stem and back of the cerebrum, consisting of two lateral lobes, and a median lobe. Its primary functions include muscle coordination and maintenance of equilibrium.

Cerebrospinal fluid (CSF)—Clear fluid that circulates in the brain and spinal cord to nourish, cushion, and maintain uniform pressure.

Hydrocephalus—Excess accumulation of cerebrospinal fluid in and around the brain, causing increased pressure.

Magnetic resonance imaging (MRI)—A technique that uses magnetic fields and radio waves to create detailed images of internal body structures and organs, including the brain.

Myelomeningocele—A sac protruding through an abnormal opening in the spinal column.

Posterior fossa—The area at the base of the skull attached to the spinal cord.

Spina bifida—An abnormal opening in the spine.

Syringomyelia—Excess fluid in the spinal cord.

- choking
- weakness
- limb paralysis
- developmental delays

Some people with Arnold-Chiari malformations have difficulty swallowing. They may report that food “catches” in their throat when they swallow. Other symptoms can include:

- pain in the neck or upper arm, which is often more severe on one side of the body
- tingling, burning, numbness, or sensations of “pins and needles”
- lightheadedness
- fainting
- weakness in an arm, a hand, or the legs
- unsteadiness or leaning to one side
- uncontrolled shaking or trembling
- difficulty walking

QUESTIONS TO ASK YOUR DOCTOR

- What type of Arnold-Chiari malformation do I have?
- Are there treatments other than surgery?
- Am I a candidate for a clinical trial?
- What is the prognosis for my type of malformation?
- What type of research is being conducted on Arnold-Chiari malformation?

- visual problems, including blurred vision, double vision, blind spots, eye pain, or rapid eye movement
- hearing impairment or ringing in the ears

Diagnosis

Arnold-Chiari malformation is diagnosed with a complete neurologic exam and magnetic resonance imaging (MRI), computed tomography (CT) scans, or x-rays. An MRI uses magnets and radio waves to produce a picture of the brain and can reveal crowding between the brain and spinal cord. The length of brain stem located in the spinal canal is measured. Analysis is used to evaluate the flow of CSF in the brain and spinal cord.

Treatment and management

Treatment depends on symptoms and the degree of pressure on the brain. Arnold-Chiari malformation may be treated with surgery to remove a small portion of the bone at the base of skull to enlarge and decompress the posterior fossa and relieve pressure on the cerebellar area. Surgery may also be required to correct the flow of CSF and to prevent progressive damage to the central nervous system. Multiple surgeries are sometimes required.

Other treatments include:

- drugs to manage headaches, pain, and other symptoms
- physical or occupational therapies for improving muscular coordination and trembling
- speech therapy for speech or swallowing problems

Clinical trials

Updated clinical-trial information on Chiari malformation and related conditions can be found at <http://clinicaltrials.gov>.

Prognosis

Prognosis depends on the type of Arnold-Chiari malformation and its severity. Patients with type I who undergo surgery to treat symptoms have an excellent long-term prognosis, although full recovery may take several months. Prognosis for type II depends on the severity of the myelomeningocele and spina bifida. Many patients with more severe forms may improve with surgery, although any paralysis is usually permanent.

Arthrogryposis multiplex congenita

Definition

Arthrogryposis multiplex congenita (AMC) is a term used to describe the presence of two or more (multiplex) joint contractures (arthrogryposis) present at birth (congenita). A joint contracture is a limitation of the normal range of motion of a joint. AMC is a clinical finding, an observation made during examination, not a diagnosis.

Description

Arthrogryposis is a finding in more than 300 conditions. The conditions are classified based on the presence or absence of neurological problems such as intellectual disability or brain malformations. If there are no neurological issues, then the AMC may be caused by amyoplasia, distal arthrogryposis, connective tissue disorders, or fetal crowding. If neurological problems are present, then the condition may be caused by a central nervous system abnormality or muscular disease. AMC disorders are not progressive, meaning the symptoms do not worsen with age.

Genetic profile

Various forms of arthrogryposis have been traced to a variety of gene mutations and inheritance patterns. Amyoplasia is typically sporadic, and does not run in families. Most of the distal arthrogryposes are inherited in an autosomal dominant pattern. If a person is affected with the condition, they have a 50% chance to pass it to each child. The chromosomal location of many of the DAs are known, and genetic testing is available.

In about 30% of cases of AMC, a genetic cause can be identified. Genetic syndromes are inherited in various ways with a recurrence risk from low to 50%. Genetic testing is available for many genetic syndromes. Recurrence risks with chromosomal changes can vary as well and are specific to the chromosomal change in the family. AMC may also be caused by a combination of unknown genetic and environmental factors and have a minimally increased recurrence risk. Environmental causes would be associated with a low recurrence risk assuming another fetus is not exposed to that same environmental factor. Often the cause for AMC is not known. Thorough testing will help identify a diagnosis. Genetic counseling can be provided to describe the recurrence risks in the family.

Demographics

Arthrogryposis occurs in approximately one in every 3,000 live births. Most cases of arthrogryposis are caused by a lack of normal joint movement during fetal

development. For this reason, cases of non-genetic arthrogryposis are more frequent in multiple-birth pregnancies than in single-birth pregnancies. Most forms of arthrogryposis are not known to affect one sub-population more than another. All forms of AMC appear to affect males and females at the same rate, with the exception of the x-linked forms, which are more common in males.

Signs and symptoms

The symptoms of AMC are primarily immobility of two or more joints. The most common joints affected are those in the fingers and toes. Less commonly affected joints are the knees and elbows. Rarely affected joints are the jaws, hips, and shoulders.

Neurological Features Absent

"Amyoplasia" means absence of muscle development and is the most common form of arthrogryposis without neurological symptoms; it is generally sporadic in appearance. Amyoplasia is characterized by contractures of the wrists, elbows, and knees, an abnormal internal rotation of the shoulders, and clubfeet. Those with amyoplasia are more likely to have a facial hemangioma, or red birthmark, an abdominal defect like gastroschisis, and normal intelligence.

Distal arthrogryposis (DAs) are all characterized by contractures of the fingers and toes. Each type can be distinguished by specific characteristics:

- Type 1a DA: camptodactyly, clubfeet that point inward and down (talipes equinovarus).
- Type 2 DA: down-slanting palpebral fissures (the line from the inner corner of an eyelid to the outer corner), a small mouth with pursed lips, malformations of the nose that cause a whistling sound when breathing, scoliosis, and some instances of mild developmental delays. This type is also known as Freeman-Sheldon Syndrome.
- Type 2b DA: consists of the characteristics of Type 2 with the addition of earlobes that are attached to the skin of the face, prominent nasolabial folds, and a permanent bending of one or more fingers (camptodactyly). This form is also called Sheldon-Hall Syndrome.
- Type 3 DA: cleft palate, talipes equinovarus, camptodactyly, short stature, and vertebral abnormalities.
- Type 4 DA: short stature, an abnormally short neck, immobile facial expressions, camptodactyly, and the lack of the normal prominent creases (flexion creases) on the palms of the hands.
- Type 5 DA: contractures of the arms and legs, limited eye movement, deep-set eyes, and abnormal coloring of the retina of the eye.

KEY TERMS

Amniocentesis—A procedure performed during pregnancy to obtain amniotic fluid. A needle is inserted into the maternal abdomen and amniotic sac and fluid is withdrawn. Fetal cells found in the fluid can be used for genetic studies.

Amniotic fluid—The fluid that surrounds a developing baby during pregnancy. Having an adequate amount of amniotic fluid is important for fetal muscle and joint development.

Amyoplasia—The most common form of arthrogryposis multiplex congenita, characterized by sporadic and recurrent contractures of the wrists, elbows, and knees; an abnormal internal rotation of the shoulders; and clubfeet.

Arthrogryposis—Abnormal joint contracture.

Camptodactyly—An abnormal permanent bending of one or more fingers or toes.

Computerized tomography (CT)—A series of x rays combined to provide a cross section view of bones and soft tissue.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Distal arthrogryposis—A disorder characterized by contractions of the muscles in the hands.

Electromyography—An electrical recording of muscle activity used to diagnose neuromuscular disease.

Flexion creases—The lines on the palms of the hands and the soles of the feet from normal bending of these body parts. Some individuals affected with arthrogryposis lack these characteristic lines.

Gastroschisis—An opening in the abdomen near the umbilical cord that allows the intestines to protrude outside the body.

Magnetic resonance imaging (MRI)—A method of visualizing organs and tissues with a magnetic field and radio waves.

Palpebral fissures—The opening between the upper and lower eyelids.

Scoliosis—An abnormal, side-to-side curvature of the spine.

Talipes equinovarus—A type of clubfoot characterized by a downward and inward-pointing foot.

- Type 6 DA: camptodactyly, an abnormally small head (microcephaly), and hearing loss caused by an abnormality of the auditory nerve (sensorineural hearing loss).
- Type 7 DA: camptodactyly when an affected individual attempts to open the hand, short stature, abnormally short muscles in the legs, and an inability to open the mouth completely (trismus).
- Type 8 DA: contractures of the wrist or ankles or both, short stature, and scoliosis.
- Type 9 DA: lack of muscle tone and development, abnormally low shoulder-to-shoulder width to body height ratio (marfanoid habitus), severe outward curvature of the spine in the neck and upper back (kyphoscoliosis), and contractures of the hips and shoulders.
- Type 10DA: plantar contractures or those involving the feet and ankles.

The most serious forms of DA are types 6 and 9.

Fetal crowding is another cause of AMC. A low amount of amniotic fluid around the fetus, more than one fetus, a septation of the uterus, or growths in the uterus can all result in less space for the fetus to move.

Neurological features present

When neurological features are present, then genetic or infectious causes are more likely. In these cases, the contractures are more often unilateral rather than symmetric. Genetic causes of AMC include changes in the number or structure of chromosomes, or packages of genetic information found in the cells. For instance, a deletion or rearrangement of chromosomal material or an extra chromosome may cause AMC. There are also many single-gene disorders associated with AMC. These conditions can be inherited in a variety of ways. One example is X-linked spinal muscular atrophy. Some infections (rubella, varicella, cytomegalovirus, toxoplasmosis) or maternal conditions are also associated with an increased risk for AMC. If a mother is affected with myasthenia gravis, then there is an increased risk for AMC. Children born with muscular disorders like myotonic dystrophy and connective tissue disorders like pterygium syndrome are also more prone.

Diagnosis

A diagnosis of AMC is indicated by the presence of two or more joint contractures present from birth. The symptoms that are present allow the differential diagnosis

QUESTIONS TO ASK YOUR DOCTOR

- What is the likely cause for AMC in this case?
- What other clinical features may be present with the diagnosis for AMC in this case?
- What is the recurrence risk with the particular diagnosis of AMC in this case?
- What are the surgical risks?
- What form of treatment do you find more beneficial, splints, braces, or removable casts?
- How many hours a day should a splint, brace, or removable cast be worn while my child is awake?
- How does massage therapy benefit this condition?

among the many causes of AMC. Sometimes AMC is noted on a prenatal ultrasound. Some of the typical findings are lack of motion, unusual position of joints, joints that are fixed into position, extra fluid in the brain, small growth, and scoliosis. When AMC is suspected during a pregnancy, prenatal testing like amniocentesis may be offered for more information about a possible diagnosis. By collecting some of the fetal cells, it is possible to view the chromosomes of the fetus and perform a more detailed genetic study called a comparative genomic hybridization. When a child is born with contractures, it is important to obtain x rays of all joints as well as the pelvis and spine. In addition, imaging studies such as a computerized tomography (CT) or magnetic resonance imaging (MRI) may provide more information about the brain and muscles. Electromyography can be useful in identifying neuromuscular disorders. Blood work for viral and genetic studies can also be performed. If an infant or child dies, an autopsy can be considered for more information towards a diagnosis.

Treatment and management

A multi-disciplinary team approach is best for those with AMC. Members of the team should include a pediatrician, neurologist, orthopedist, and geneticist. Physical therapy has proven an effective treatment for almost all forms of AMC. Splints, braces, and removable casts are often used to improve joint positioning. In most cases, these orthopedic devices are used only at night so that proper joint mobility can be encouraged during the waking hours. Occasionally, surgery to repair foot and ankle position may be necessary, especially in the case of talipes equinovarus. Much less frequently, orthopedic surgery of the hips, knees, elbows, shoulders, and wrists is required. Tendon replacement surgery has also been successful in some individuals affected with AMC.

Prognosis

Prognosis for those with AMC depends on the underlying cause of the condition. In cases of AMC that do not involve complications of the central nervous system, the outlook is quite good and lifespan is not shortened. Most individuals can achieve a sufficient range of motion in their affected joints to live healthy, complete lives. AMC is non-progressive; therefore, once a joint contracture has been repaired through physical therapy, surgery, or both, it will generally not return to a state of abnormal contracture.

When AMC is complicated by involvement of the central nervous system, approximately half of affected individuals die in infancy. Among the surviving half, many have varying degrees of intellectual disability.

Many families find it helpful to connect to other families dealing with a similar condition. One national support organization for those affected with AMC and their families is called Avenues. They offer resources, research information, updates, publications and ways to connect to other families. Another similar group is called Arthrogryposis Multiplex Congenita Support, Inc. It sponsors events and newsletters and hosts an annual conference.

Arthropathy-camptodactyly syndrome

Definition

Arthropathy-camptodactyly syndrome is a disorder affecting the joints of the fingers. “Arthropathy” refers to a disease or disorder affecting a joint, and camptodactyly is a congenital condition, meaning present at birth, characterized by the bending of one or more fingers.

Description

In people with arthropathy-camptodactyly syndrome, one or more fingers are bent. Other joints may be affected as well. Some children with arthropathy-camptodactyly syndrome also have swollen knees and ankles and hip pain.

Problems with the pericardium, the sac that surrounds the heart, are also common in children with arthropathy-camptodactyly syndrome. In many cases, the pericardium is removed, a surgical procedure called pericardiectomy.

Genetic profile

Arthropathy-camptodactyly syndrome typically occurs in children (both male and female) whose parents are related by blood. In one case, it was determined that the parents of children with arthropathy-camptodactyly syndrome shared the haplotype A1-Bw21. The gene map locus 1q24-q25 is also implicated.

Demographics

Cases of arthropathy-camptodactyly syndrome have been diagnosed in Canada, India, Mexico, Newfoundland, Pakistan, Saudi Arabia, and Turkey, as well as in African Americans.

Signs and symptoms

People with arthropathy-camptodactyly syndrome have a bend in the joint of one or more fingers. Other symptoms include swollen knees and ankles and hip pain.

KEY TERMS

Allele—One of two or more alternate forms of a gene.

Arthropathy—Any disease or disorder that affects joints.

Camptodactyly—A condition characterized by the bending of one or more fingers.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Congenital disorder—Refers to a disorder that is present at birth.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Haplotype—The set of alleles on one chromosome.

Locus—The physical location of a gene on a chromosome.

Inflammation of the sac lining the heart (pericarditis) is another observed symptom, often accompanied by chest pain. The pain is usually sharp and felt behind the breast bone (sternum).

Diagnosis

Aside from the physical observation of bent fingers, no test is presently available to confirm diagnosis.

Treatment and management

Surgery can correct the bent fingers disorder that characterizes arthropathy-camptodactyly syndrome. Removal of the tendon sheaths in the affected fingers can help keep them mobile. Removal of the membranes surrounding a joint (synovectomy) of other body joints, such as knees, can also help maintain mobility.

In at least one case, a bent finger straightened without intervention.

QUESTIONS TO ASK YOUR DOCTOR

- What do you expect will be the outcome of surgery?
- What are the risks associated with surgery?
- What are the chances that the joint bending will resolve without surgery?
- What are the risks and expected benefits of pericardiectomy?

Pericardiectomy is often performed to relieve the pericarditis often associated with the disorder.

Prognosis

Case studies show that children with arthropathy-camptodactyly syndrome have lived into their teens. There is reason to believe that with the proper treatment, the disorder is not life shortening.

Asperger syndrome

Definition

Asperger syndrome (AS) is the name formerly applied to some individuals with autism spectrum disorder (ASD) who are considered to function at a significantly higher level than most people with ASD. AS was first described by Hans Asperger, an Austrian psychiatrist, in 1944. Asperger's work was unavailable in English before the mid-1970s; as a result, AS was often unrecognized in English-speaking countries until the late 1980s. Before the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV 1994), there was no official definition of AS. While AS was defined in the DSM-IV, the most recent revision of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), released in 2013, does not contain Asperger syndrome, which is now included under the umbrella of Autism Spectrum Disorders (ASD). However, this source includes a table by which ASD can be categorized into three levels, including Level I, which requires support; Level 2 which requires substantial support, and Level 3, for which the individual with ASD requires very substantial support. With regard to ASD, individuals with AS would be categorized as Level 1, requiring the least amount of support. Prior to the DSM-5, Asperger syndrome was sometimes referred to as high-functioning autism (HFA), as it is considered to be the mildest form of AS and thus requires the lowest level of needed assistance.

Description

Children with AS learn to talk at the usual age and often have above-average verbal skills. They have normal or above-normal intelligence. They also have the ability to take care of themselves, although personal interactions with others may be confusing and challenging for them. The distinguishing features of people with ASD are problems with social interaction, particularly reciprocating and empathizing with the feelings of others; difficulties with nonverbal communication (e.g., understanding and interpreting facial expressions and body language); peculiar speech habits that include repeated words or phrases, and sometimes a flat, emotionless vocal tone; a fascination with obscure or limited subjects often to the exclusion of other interests; sometimes clumsy and awkward physical movements; and odd or eccentric behaviors (hand wringing or finger flapping; swaying or other repetitive whole-body movements; and watching spinning objects for long periods of time).

Risk factors

Research clearly indicates a hereditary risk for ASD, very few genes involved have been identified. According to Seyed Alireza Hosseini and Mohammed Molla, genomic sequencing data indicates that as many as one thousand genes may be implicated in a predisposition to ASD. Some researchers have noted that people with AS and other disorders related to ASD may carry variations of the gene *GABRB3*, which is related to differing capacities for empathy; however, much further research is needed. Researcher Dan Bai and colleagues have found an 80% genetic risk for ASD in a very large study involving children in five countries, including Denmark, Finland, Israel, Sweden, and western Australia. The researchers analyzed data from children from 1998 through 2011, which included two million children. Of those, 22,156 were diagnosed with ASD. This study provided strong evidence that most of the risk for ASD stems from genetics rather than environment. Of course, the environment also plays a role in ASD, including the prenatal environment. In a study of more than 273,000 pregnant women and their children in Sweden by H. Gardener and colleagues, the researchers found that the women who took multivitamins, iron, and folic acid supplements during pregnancy had children with about half the rate of ASD, compared to the mothers who did not take these supplements, or 0.26%, versus 0.48% among the mothers who did not take nutritional supplements. This is a tiny difference in that both were less than 1%; however, most pregnant women, upon hearing this data, would be willing to take supplements during pregnancy to decrease their odds of having a child with ASD.

Most children with AS are diagnosed between the ages of five and nine years of age; however, some are not diagnosed until adolescence or adulthood. In addition, misdiagnoses are common. AS has been confused with other neurological disorders, such as Tourette syndrome as well as attention deficit hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), or obsessive-compulsive disorder (OCD).

Demographics

Based on an analysis of the prevalence of ASD in the United States by Matthew J. Maenner and colleagues, published in 2016, one in 54 children is diagnosed with ASD by the age of eight years. The researchers analyzed data from 11 states, including Arizona, Arkansas, Colorado, Georgia, Maryland, Minnesota, Missouri, New Jersey, North Carolina, Tennessee, and Wisconsin. They found that boys had four times the rate of ASD prevalence of girls. There were few racial differences in the prevalence of ASD; for example, the researchers found about the same prevalence of ASD in non-Hispanic whites and non-

Hispanic Black children; however, there was a lower prevalence among Hispanic children. The reasons for this are unknown. The researchers also found the prevalence of ASD varied considerably from state to state; for example, the rate (not a percentage) was 13.1 per 1,000 children in Colorado, and it was a much higher rate of 31.4 per 1,000 children in New Jersey. Some studies suggest that the incidence of autism spectrum disorders is increasing. Others suggest that increased awareness and broadening of the diagnostic criteria play a role in the perceived increase.

Research studies have made no connection between Asperger syndrome and childhood trauma, abuse, or neglect. Nor does receiving childhood immunizations increase the risk for the development of ASD.

Signs and symptoms

In young children, the symptoms of AS typically include problems recognizing and responding to social cues and understanding the basics of interacting with other children. The child may wish to have friendships yet struggle to make friends. Behaviors that are easy for other children, such as appropriate eye contact and interpreting body language, are baffling to people with ASD. Another issue is that children with AS or ASD may be bullied in school, largely because of their differences in behavior. However, Brooke N. Winchell and colleagues note that when children who do not have AS or ASD have the opportunity to learn about the disorder, they have more positive attitudes toward people with ASD. The authors assert that similarities between children with AS and others should be emphasized to children who are learning about AS, and that perceptions of lower ability or status should be minimized. In addition, peers should learn about ways to interact with people with ASD, and the strengths of individuals with ASD should be pointed out. These actions can decrease the risk for bullying.

Most children with Asperger syndrome are diagnosed during the elementary school years, because the symptoms of the disorder become more apparent at that point. They include:

- Poor pragmatic language skills. This phrase means that the child does not use the right tone or volume of voice for a specific context and does not understand that using humorous or slang expressions also depends on social context.
- Problems with hand-eye coordination and other visual skills.
- Problems making eye contact with others.
- Learning difficulties, which may range from mild to severe.
- Tendency to become absorbed in a particular topic and not know when others are bored with conversation about

it. At this stage in their education, children with AS are likely to be labeled as “nerds.”

- Repetitive behaviors. These include such behaviors as counting a group of coins or marbles over and over, reciting the same song or poem several times, or buttoning and unbuttoning a jacket repeatedly.

Adolescence is one of the most painful periods of life for young people with Asperger’s, because social interactions are more complex in this age group and require more subtle social skills. According to author Tony Attwood, the person with AS is likely to experience great difficulty with planning and organizing, skills increasingly that are needed in school and that affect grades when they are absent. In their teenage years, memorized information becomes less important than learning to analyze the meaning of the information. In addition, teens are often expected to work in groups or with partners, which is an area where adolescents with AS have difficulty.

Little research has been done regarding adults with AS. Some have serious difficulties with social and occupational functioning, but others are able to finish their schooling, join the workforce, and marry and have families.

Diagnosis

There are no blood tests or brain scans that can be used to diagnose AS. However, as of 2021, the National Institutes of Health is actively conducting brain studies of the infant siblings of children diagnosed with ASD to see whether there are identifiable brain changes in the younger child that may be predictive for the later development of ASD. While the DSM-IV (1994) had an “official” list of symptoms for the disorder, the DSM-5 (2013) placed Asperger syndrome under the more-encompassing term of autism spectrum disorders. Prior to this change, having two separate categories with significant overlap of symptoms—Asperger syndrome and high-functioning autism—made the diagnosis of either condition both difficult and inexact. Having a single encompassing category and recognizing that symptoms fall along a spectrum of behavior are anticipated to aid research efforts.

Although most children with AS are diagnosed between ages five and nine, many are not diagnosed until adulthood. Misdiagnoses are common.

The original inclusion of AS as a separate diagnostic category in DSM-IV was justified on the basis of a large international field trial of over one thousand children and adolescents. Nevertheless, the diagnosis of AS is also complicated by confusion with such other diagnostic categories as “high-functioning (IQ 70) autism,” or HFA, and “schizoid personality disorder of childhood.” With regard to the latter, AS is not an unchanging set of personality traits but instead has a developmental dimension.

DSM-IV criteria for Asperger syndrome

DSM-IV specified six diagnostic criteria for AS:

- The child’s social interactions are impaired in at least two of the following ways: markedly limited use of nonverbal communication, lack of age-appropriate peer relationships, failure to share enjoyment, interests, or accomplishment with others, lack of reciprocity in social interactions.
- The child’s behavior, interests, and activities are characterized by repetitive or rigid patterns, such as an abnormal preoccupation with one or two topics, or with parts of objects; repetitive physical movements; or rigid insistence on certain routines and rituals.
- The patient’s social, occupational, or educational functioning is significantly impaired.
- The child has normal age-appropriate language skills.
- The child has normal age-appropriate cognitive skills, self-help abilities, and curiosity about the environment.
- The child does not meet criteria for another specific PDD or schizophrenia.

DSM-5 criteria for autism spectrum disorders

DSM-5 specifies five diagnostic criteria for Autism Spectrum Disorder:

- A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history:
 1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
 2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
 3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.
- B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history:
 1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypes, lining up toys or flipping objects, echolalia, idiosyncratic phrases).

2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).
 3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
 4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g. apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).
- C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).
- D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
- E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

Brain imaging findings

As mentioned earlier, in 2021, the NIH is studying the brain scans of the infant siblings of children with ASD, looking for possible changes that may be predictive for the later development of the disorder.

Treatment and management

As of 2021, there is no cure for AS or HFA (or ASD), and there is no prescribed regimen for all affected patients. Specific treatments are based on the individual's pattern of symptoms, particularly those that are problematic to the individual, such as depression, anxiety, hyperactivity, or aggression.

Traditional

Many children with ASD take multiple medications. According to the DSM-5, an estimated 70% of individuals with ASD have one other psychiatric disorder, while 40% have two or more such disorders. Often, the medications that people with AS or ASD take are directly related to the

QUESTIONS TO ASK YOUR DOCTOR

- Can Asperger syndrome be cured?
- What treatment options are available?
- How do they differ in terms of expected outcomes?
- Is drug therapy required?
- What may have caused my child to have Asperger syndrome?
- Do you recommend psychotherapy?
- Should my child be tested for learning disabilities?
- What is the long-term prognosis for my child?

symptoms that are most problematic for them, such as aggression, anxiety, depression, or hyperactivity. In an analysis by Aliya F. Geroe and colleagues, the medication use among 26,722 individuals with ASD was analyzed. Most of the subjects were male (78%), and the average age of the subjects was 14 years. There was a high variability in the medications used, but at least 15% of the prescribed drugs were medications for ADHD.

Drugs

In general, the drugs recommended most often for children with AS include psychostimulants (such as methylphenidate) or antipsychotics for anger or aggression, as well as selective serotonin reuptake inhibitors (SSRIs) for treating rituals and preoccupations or anxiety symptoms.

Clinical trials

As of 2021, many clinical trials for the treatment of autism spectrum disorders are being sponsored by the National Institutes of Health (NIH) and other agencies. Clinical trial information is constantly updated by NIH. The most recent information on autism spectrum disorder trials can be found at: <https://clinicaltrials.gov>.

Prognosis

AS or HFA is a lifelong but stable condition. The prognosis for the intellectual development of children with AS is generally good. An increasing number of school districts are becoming equipped to meet their special social needs. Effective prevention of Asperger disorder and autism spectrum disorders awaits further genetic mapping, together with ongoing research on the structures and functioning of the brain.

Asplenia

Definition

Asplenia in the strict sense is not a genetic disorder but a medical condition that may or may not have a genetic cause. Asplenia may be either congenital (present at birth) or acquired (developed later in life, most often as the result of surgical removal of the spleen). The term "asplenia" literally means the absence of a spleen or of splenic function. The spleen may be completely absent in congenital asplenia. However, in some subtypes of congenital asplenia, it may be present but not fully developed. It is then said to be hypoplastic.

Some forms of congenital asplenia are linked to disorders in the right-left distribution of the internal organs. Individuals with these conditions often have problems with other organs and organ systems. A related condition is polysplenia, which literally means multiple spleens. Both of these conditions affect the placement and development of the organs inside the body. There is controversy over whether asplenia and associated syndromes like polysplenia are actually different aspects of the same condition—referred to as heterotaxy syndrome—or separate and distinct syndromes. The ongoing lack of a standardized approach to diagnosis and reporting of these syndromes has been noted in several reports published in 2014. Other names for these syndromes include Ivemark syndrome, right isomerism sequence, right atrial isomerism (RAI), bilateral right-sidedness sequence, splenic agenesis syndrome, and asplenia with cardiovascular anomalies.

Description

The human body has laterality; it has a right and a left side. Normally, inside the human body, the right side and the left side are different with respect to the presence of unpaired organs. Several organs inside the body are placed asymmetrically, meaning that an unpaired organ like the spleen may be located on one side of the body but not on the other. In addition, there are some organs that are found on both sides of the body, but have differences that distinguish the right-side organ from its partner on the left side. The right and left sides of the heart are an example of this

pattern, as each side of the heart has a different function. The right side pumps blood to the lungs to be oxygenated. The left side receives the oxygenated blood from the lungs and pumps it through the aorta to the rest of the body.

Disturbances of the normal pattern of laterality of the internal organs in the chest and abdomen are called laterality defects. In asplenia, the position, location, appearance, and performance of some of the internal organs are altered. Organs can often be found on the wrong side of the body and/or have structural defects. Furthermore, in most people the right and left organs are different. In people with asplenia, both organs may appear to have the same structure. For example, their heart may have two left sides or two right sides.

Genetic profile

In most families, asplenia is believed to occur sporadically. In other words, it occurs for the first time in a family and has no known or identifiable pattern of inheritance. There appear to be two different types of congenital asplenia: isolated congenital asplenia or ICAS and congenital asplenia. ICAS is an extremely rare condition marked by the complete absence of the spleen. Congenital asplenia is associated with failure to establish the normal right/left organ placement and symmetry during the process of embryonic development. These disorders of normal laterality are grouped together as heterotaxy syndromes.

Isolated congenital asplenia (ICAS)

Isolated congenital asplenia or ICAS is distinct from the other forms of asplenia known as heterotaxy syndromes. ICAS was traced in 2013 by a team at Rockefeller University in New York to seven different mutations in the *RPSA* gene on chromosome 3p21. It has been shown to have an autosomal dominant pattern of inheritance, which means that only one abnormal gene from either parent is sufficient to produce ICAS in the offspring. The discovery establishes that the *RPSA* gene is essential to the normal development of the spleen in humans.

Heterotaxy syndromes

Heterotaxy syndromes appear to be inherited in three different patterns, each involving different genes.

AUTOSOMAL RECESSIVE. Ivemark syndrome is considered an example of asplenia inherited in an autosomal recessive manner. The condition has been traced to mutations in the *GFDI* gene on chromosome 19p12. In addition to Ivemark's case studies, there have been several couples described in the medical literature who have more than one child diagnosed with asplenia. In several of these families, the parents were related to each other. Individuals who are consanguineous (related to each

other by blood) are more likely to carry some of the same defective genes. Therefore, these families illustrate that some forms of asplenia can be inherited in an autosomal recessive manner. In 2012, a team of researchers in Jerusalem identified a mutation in the *CCDC11* gene on chromosome 18q21.1 as responsible for congenital asplenia in two brothers born to consanguineous parents. The researchers established that the gene is inherited in an autosomal recessive pattern.

Individuals who have an autosomal recessive condition have both genes in a pair that do not work as expected or are missing, thereby causing the disease. One defective gene is inherited from the mother, and the other is inherited from the father. These parents are called carriers of that condition. When two people are known carriers for an autosomal recessive condition, they have a 25% chance with each pregnancy of having a child affected with the disease.

Autosomal dominant

There are a few families in which congenital asplenia other than ICAS appears to be inherited in an autosomal dominant or X-linked manner. In autosomal dominant inheritance, only one gene in the pair needs to be abnormal to cause symptoms of the condition. In families in which asplenia appears to be inherited in an autosomal dominant manner, family members who carry the same defective gene can have different symptoms and the severity of the condition may vary. In autosomal dominant inheritance, if an individual carries the defective gene, he or she has a 50% chance of passing the gene on with each pregnancy. Congenital asplenia inherited in an autosomal dominant pattern has been traced to mutations in the *CFC1* gene on chromosome 2q21 and in the *ACVR2B* gene on chromosome 3p22.2.

X-LINKED. In families in which asplenia appears to be inherited in a X-linked manner, the gene causing the condition is located on the X chromosome. Mutations in the *ZIC3* gene on the X chromosome at Xq26.3 have been identified as causing X-linked forms of congenital asplenia. Because women have two X chromosomes, if a woman inherits the defective gene on one of her X chromosomes, typically she will not have any symptoms of asplenia or will have a milder form of the condition. A woman who carries the X-linked form of asplenia will have a 50% chance of passing on that defective gene with each pregnancy.

Because normal males have one Y chromosome and one X chromosome, a son who inherits the defective *ZIC3* gene will be affected with the condition. Men who have an X-linked form of asplenia will always pass on their X chromosome containing the defective gene to all their daughters, who will be carriers of the condition. In these families, asplenia will never be passed from the father to the son,

KEY TERMS

Anomalous—Irregular or different from normal.

Anomalous venous return—Normally, the veins that bring blood containing oxygen from the lungs to the heart (called pulmonary veins) are connected to the left atrium. In this situation, the pulmonary veins are connected to the right atrium.

Asplenia—The absence of the spleen or of normal splenic function in the body. It may be either congenital or acquired.

Atrium (plural, atria)—One of the two upper chambers of the heart. Typically, there are two atria, one on the right side of the heart and one on the left.

Atrial septal defect (ASD)—An opening between the right and left atria of the heart.

Congenital—Present at birth.

Cyanosis—A bluish color of the skin that results from insufficient oxygen in the blood transported throughout the body.

Echocardiography—An ultrasound examination targeted at the heart and performed by a cardiologist or an individual trained at detecting differences in the structure of the heart. The product of the examination is an echocardiogram.

Heterotaxy—A condition in which the thoracic and abdominal viscera are arranged abnormally across the left-right axis of the body. It is also referred to as heterotaxy syndrome or visceral heterotaxy.

Isomerism—In human anatomy, a condition in which organs normally found on only one side of the body are found on both sides. In reference to the heart, isomerism refers to a condition in which the heart has either two right sides with two right atria or two left sides with two left atria.

Ivemark syndrome—A rare disorder characterized by cardiovascular anomalies as well as asplenia or hypoplasia of the spleen. It is named for Biörn Ivemark (1925–2005), the Swedish pediatrician who first identified the syndrome in 1955.

Laterality—The right-left distribution of the internal organs.

Malrotation—An abnormality that occurs during the normal rotation of an organ or organ system.

Pulmonary atresia—A congenital malformation of the pulmonary valve in which the opening of the valve fails to develop. As a result, blood cannot flow out of the heart through the pulmonary artery to the lungs to be oxygenated.

Pulmonary stenosis—Narrowing of the pulmonary valve of the heart, between the right ventricle and the pulmonary artery, limiting the amount of blood going to the lungs.

Syndrome—A group of signs and symptoms that collectively characterize a disease or disorder.

Transposition of the great arteries (TGA)—A reversal of the two great arteries of the heart, causing oxygenated blood to be carried back to the lungs and deoxygenated blood to be transported throughout the body.

Truncus arteriosus—A condition in which a structure present during fetal development fails to develop normally into two separate structures, the aorta and the pulmonary trunk. Thus, there is only one arterial trunk structure leading from the heart instead of two. Often there is a ventricular septal defect (VSD) present.

Ventricular septal defect (VSD)—An opening between the right and left ventricles of the heart.

since men give their sons a Y chromosome. If a woman who carries an X-linked condition passes the X chromosome containing the non-working gene to a daughter, then that daughter will be a carrier like her mother.

The pattern of inheritance of asplenia in a family is usually not obvious when there is only one individual diagnosed with the condition. Based on the families and studies performed on asplenia, the chance of a couple who have one child with asplenia having another child with the condition is approximately 5% or less. This chance may be higher if it is determined that asplenia is part of heterotaxy syndrome, since there are a wider range of symptoms associated with that condition. Furthermore, if more than one

family member has the diagnosis of asplenia, the chance of it occurring again in the family is based on the pattern of inheritance that the condition appears to be following.

Demographics

ICAS is a very rare condition, estimated to have an incidence of 0.5 per 1 million births. The incidence of other forms of congenital asplenia is higher than that of ICAS, but still low, approximately 1 in 10,000 to 1 in 20,000 live births. Some researchers, however, think that the condition is underdiagnosed because newborns with congenital asplenia have high mortality rates and may not be autopsied.

More males are affected with the condition than females. Asplenia also accounts for 1%–3% of all congenital heart defects and 30% of newborns who die of malformations of the heart. Congenital asplenia appears to occur with equal frequency in all races and ethnic groups.

Signs and symptoms

Almost all individuals with congenital asplenia have an abnormal or absent spleen. The most common symptom of isolated congenital asplenia or ICAS is primary immunodeficiency. Most affected individuals die in early childhood of severe bacterial infections.

In the various heterotaxy syndromes, however, organ systems in addition to the spleen and the immune system are commonly affected.

Abdominal organs

SPLEEN. As the name of the condition implies, the spleen is always affected in asplenia. The spleen in individuals with asplenia either is absent or does not develop completely (hypoplastic spleen). Because the spleen is involved in the body's immune system, these infants can have an abnormal immune system, which increases their risk for developing an infection.

DIGESTIVE TRACT DISORDERS. There are several abnormalities that can occur with the digestive tract in individuals with asplenia. The most common digestive tract disorder associated with asplenia is malrotation of the intestine. Sometimes a digestive tract problem will present with symptoms of an obstruction in the digestive system, requiring emergency surgery.

STOMACH. Most individuals with asplenia have their stomach located on the right side or in the center of the body instead of the left. In addition, individuals with asplenia can have a “twisted” stomach that could result in an obstruction in their digestive system and impair the blood supply to the stomach (gastric volvulus).

LIVER. Normally, the liver is located on the right side of the body and the shape of the liver is not symmetrical. In asplenia, there can be isomerism of the liver—it may be located in the middle of the body, or located on the left side with the larger half of the liver located in the upper left side of the abdominal area.

GALLBLADDER. The gallbladder may also be located in the middle of the body in individuals with asplenia.

Heart

Many infants with asplenia first present with cyanosis and severe respiratory distress. These are symptoms often seen in individuals who have a heart defect. Most

individuals with asplenia have a defect in the structure and/or the position of their heart.

Typically, the heart is divided into two sides, a left and right, with each side containing two chambers, called ventricle and atrium. The left and right sides of the heart are different from each other in their structure and function. The right side of the heart pumps blood through the pulmonary artery to the lungs to receive oxygen. The left side of the heart receives the oxygenated blood from the lungs and pumps it to the rest of the body. In congenital asplenia, the affected individual may have a heart with two left sides or two right sides.

A common heart defect often seen in asplenia is anomalous pulmonary venous return, which occurs when the pulmonary veins are connected to the right atrium instead of the left atrium. This malformation causes the oxygenated blood to be pumped back to the lungs instead of the body. Sometimes there is a hole between the right and left atria (called atrial septal defect or ASD) that allows some of the oxygenated blood into the left atrium and pumped to the rest of the body.

Other heart defects frequently seen in individuals with asplenia include: common atrioventricular canal, common atrial canal, persistent truncus arteriosus, pulmonary stenosis or atresia, single ventricle in the heart, and transposition of the great arteries. Often there is more than one heart defect present. Furthermore, in many individuals with asplenia, the heart is located on the right side of the body instead of the left.

Lungs

Normally, the lungs are divided into lobes. The lung on the right side of the body usually has three lobes, and the left lung typically has two lobes. In asplenia, each lung usually has three lobes.

There can be abnormalities in other systems of the body as well, but they are not often seen in most individuals with asplenia. Other abnormalities associated with asplenia include kidney anomalies, extra fingers and toes, scoliosis, facial abnormalities, and central nervous system anomalies.

Diagnosis

The diagnosis of asplenia is typically made by imaging studies. There is no single radiographic study that is best for all types of asplenia. An echocardiogram of the heart can help identify any structural abnormalities and its exact position within the body. A chest x-ray can also be used to locate the position of the heart and some of the other organs in the body. Ultrasound is preferred for diagnosing ICAS. Ultrasound and CT examinations can also help determine whether there are any malformations in the abdominal organs, the position of the stomach, and

QUESTIONS TO ASK YOUR DOCTOR

- What type of congenital asplenia does my child have? Is it treatable?
- Is there a specific gene or inheritance pattern associated with my child's form of asplenia?
- What are the risks and benefits of heart surgery?
- What are the risks and benefits of digestive tract surgery?
- What specific structural abnormalities are present in my child's heart?
- Will my child's activity be restricted throughout life?

the number of lobes in the lungs. These exams can also determine the presence, appearance, and number of spleens. While an MRI can also detect the presence and position of organs inside the body, it is less commonly used because of the need for sedation and the high cost of the test, especially in children.

Testing for the presence of Heinz and Howell-Jolly bodies in the blood has been suggested as a method to screen for an absent spleen. Howell-Jolly bodies are unique cells that tend to be present in the blood of individuals who do not have a spleen, but they can also be found in the blood of individuals who have certain types of anemia. Therefore, this test should not be used as the sole diagnostic test for an absent spleen.

Some of the abnormalities seen in asplenia can be detected prenatally. Often the position of the heart and some of the heart defects can be diagnosed by fetal echocardiogram (an ultrasound examination of the fetal heart) in the late second and third trimesters of pregnancy. A fetal echocardiogram should be performed during pregnancy when a couple already has a child with asplenia. In addition, a level II ultrasound examination can detect some digestive system anomalies, such as the position of the stomach.

Treatment and management

ICAS is presently treated with prophylactic antibiotics to lower the risk of bacterial infections. The child should continue to receive antibiotic therapy as long as he or she lives.

In children with Ivemark syndrome or other forms of congenital asplenia associated with heart defects, surgery can sometimes be performed on the heart to repair the defect or defects. There are limitations to heart surgery, and it

cannot always be performed. Moreover, heart surgery is not always successful. Surgery can also be used to correct many of the digestive tract disorders.

Because the spleen is involved in the body's immune system, it is also recommended that all patients with the diagnosis of asplenia be given prophylactic antibiotics as well as pneumococcal and meningococcal vaccination. In addition, they are usually required to take prophylactic antibiotics prior to even minor surgery or dental procedures, and to be restricted from traveling to countries with high levels of infectious disease.

Prognosis

As of 2015, all known patients with ICAS died of sepsis within 23 months of birth, most of them within 12 months.

Without treatment, the prognosis of an infant diagnosed with asplenia is poor, with approximately 80% of these infants dying within the first year of life. The cause of death is usually complications from the heart defects, although many infants with congenital asplenia also die of overwhelming bacterial infections. However, with advances in heart surgery and improvements in correcting many of the digestive tract anomalies, infants with asplenia are living much longer.

Asthma

Definition

Asthma is a chronic and inherited disease resulting from an overactive immune system that causes inflammation of the lungs, coughing, wheezing, and shortness of breath. “Asthma” comes from the Greek word for “panting.” The disease results from an over-responsiveness of the respiratory system to stimulating factors like allergens. It is characterized by repeated, temporary episodes of constriction and inflammation of the airways and lungs, along with excess mucous production. Asthma attacks are characterized by severe difficulty breathing, especially when exhaling. Severe attacks that are left untreated may become fatal. An individual with asthma may be completely without symptoms between attacks.

Description

Asthma is a chronic, lifelong disease that affects the complex network of air passageways of the respiratory system. People with asthma may experience a range of symptoms from mild discomfort to life-threatening attacks that require immediate emergency treatment. The respiratory system is made up of bronchial tubes (airways) and the lungs. Asthma involves the inflammation of the bronchial tubes and lining of the lungs. The inflammation causes the airways to be overly sensitive to irritating factors, which cause constriction and obstruction to the passage of air into the lungs. People with asthma also produce excess amounts of mucus in the respiratory tract. Mucus is a normal component of respiratory function that aids in carrying irritating particles up and out of the respiratory system to be expectorated (coughed up) from the body. People with asthma produce excessive, abnormally thick mucus that interferes with breathing and contributes to the problem. Severe asthma attacks can be fatal. Persistent or chronic inflammation of the airways can cause permanent damage, which is also called airway “remodeling.” This will reduce lung function so that breathing becomes less efficient even outside of asthma attacks. People with

asthma may experience chronic wheezing, coughing, shortness of breath, and a feeling of a tightening of the chest. Medication and careful management of the disease are often necessary for maintaining normal function.

Some individuals inherit a genetic predisposition to asthma that can be triggered by a variety of environmental factors. Stimuli for triggering asthmatic symptoms include repeated exposure to irritants, such as dust mites, pet hairs, and tobacco smoke. These types of stimuli are considered allergens, or particles that trigger an allergic response. Asthma may also be induced by exercise, especially in cold climates where the respiratory system has to work harder to warm and moisten inhaled air. Some people with asthma only experience symptoms during viral infections. Both physical and psychological factors may precipitate an asthma attack.

Genetic profile

Asthma is a complex inherited disease in which a number of different genes and environmental triggers contribute to asthmatic predisposition. Children who have one parent with asthma have a 25% of having asthma, and children who have two parents with asthma have around a 50% risk. Variations in some genes influence how likely someone will be to develop asthma, while other variations influence the severity or response to treatment. In some cases, variations in different genes can cause the same symptoms. More commonly, variations in multiple genes and factors in the environment affect the risk of asthma in each person. While genes may cause a predisposition, asthma attacks are triggered by stimulating environmental factors. Variants in some asthma genes can also increase risk for other diseases, such as cardiovascular disease, cancer, or autoimmune diseases. Some researchers have postulated that asthma is an autoimmune disease. An autoimmune disease is a condition in which the immune system attacks the body because it mistakes parts of it as foreign. Similar genes can influence the risk of both allergies and asthma. Variations in some genes can decrease the risk of asthma.

Variations in over 100 different genes have been associated with asthma, although not all associations have been confirmed. Variations in the *ORMDL3*, *GSDMB*, and *GSDML* genes appear to be associated with an increased risk for childhood-onset asthma. Variations in some of the interleukin genes may increase the risk of asthma triggered by allergens. Variations in some genes, such as the *TSLP* gene, may decrease the risk of cancer.

Research studies suggest that specific symptoms experienced by asthma patients, such as the inflammation of the airways and lungs, are initiated by the action of genes that regulate the activity of the immune system. In other words, these genes control how the immune system

Asthma is a chronic disease of the respiratory system in which the airway occasionally constricts and become inflamed. An inflamed bronchus (left) and a normal one (right) are shown. (MedicalRF/Science Source)

responds to the presence of substances that can potentially trigger asthma symptoms.

Like a microscopic army, the immune system consists of a wide array of specialized cells that work together to neutralize threats to the system. Antigens are any foreign agents that invade the body and trigger such an immune response. They include disease-producing organisms, such as viruses, toxic chemicals in the environment, or allergens, such as animal dander and dust mites. In response to the identification of specific foreign antigen particles, some immune cells produce antibodies to attack them. This immune response occurs after an initial encounter with an antigen and is known as a primary immune response. The immune system recognizes past contact with specific antigens by maintaining specific levels of the antibodies that are customized to attack specific antigens. When the same antigen is encountered again, the specific antibodies that have been maintained in the body multiply and mount a stronger immune response than the primary response. This process is known as the secondary immune response.

One of the specific antibodies produced in response to allergens is a protein known as immunoglobulin E (IgE). In a normal inflammatory response, IgE recognizes

foreign antigens and initiates immune reactions against the antigen by binding to other immune cells, such as mast cells. Mast cells release chemical mediators that contribute to inflammation directly but also recruit more immune cells to the site of inflammation. The recruited immune cells also release mediators of inflammation, such as histamine, that amplify the response and cause inflammation. In people with asthma, the IgE mast cells are highly excitable, making them hypersensitive to stimulation. When foreign antigens are breathed into the respiratory system, the entire inflammatory process, including the recruitment of other immune cells that release histamine, becomes exaggerated, resulting in asthma.

People with asthma seem to produce higher levels of IgE antibodies, more hyperactive mast cells, and higher levels of consequent histamine than the general population. Histamine is a type of chemical signal that initiates the inflammatory response. It stimulates the dilation of blood vessels' walls and makes them more porous. As a result, blood fluid and proteins leak out of the blood vessels and into surrounding tissue, causing the swelling and reddening that are typical of inflammation. Inflammation involves increased blood flow to affected tissues to allow

the passage of the recruited immune cells from the blood into them. The immune cells may then dispose of the foreign particles. While this response is designed to defend the tissue from foreign invasion of harmful particles, an exaggerated response can be dangerous. In asthma, the resultant inflammation, along with the reactive constriction of the muscles in walls of the bronchial airways, narrows the air passages and causes an asthma attack.

Overactive T helper 2 (Th2) immune cells can increase the amount of IgE produced by the body. Overactive TH2 cells are linked to 80% of childhood cases and 60% of adult asthma cases. In people who are predisposed to asthma, allergens activate the Th2 cells, which produce proteins that can increase the amount of IgE antibody produced. The Th2 proteins and IgE stimulate the immune system to overact, which results in asthma symptoms. Interestingly enough, lack of exposure to childhood illnesses can contribute to the increased response of Th2 cells found in asthma. In the absence of exposure to illness, the immune system seems to produce more of these Th2 cells, which ultimately increases the production of the IgE antibody.

Another component of the immune defense is the production of nitric oxide gas (NO) by an enzyme called inducible nitric oxide synthase (iNOS). Cells lining the bronchial tubes contain this enzyme that produces NO in response to chemical signals released from immune cells. People with asthma produce an abnormally higher level of iNOS in their respiratory cells than the general population does, and they have higher levels of NO in their lungs and bronchial tubes that contribute to the disease.

Demographics

In the United States, almost 10%, or 25 million people, have asthma. In 2012, asthma resulted in approximately 1.6 million emergency visits. It affects individuals of all ages but often starts in childhood. Asthma is the most prevalent childhood chronic disease. In children, more boys than girls have asthma. Boys have a 30% higher prevalence of asthma compared to girls. In adults, the trend is reversed, with more women having asthma than men. Women have a 30% higher prevalence of asthma than men do. Within ethnic groups, non-Hispanic blacks have more asthma attacks. Furthermore, they are more likely to be hospitalized and die from asthma than are non-Hispanic whites. Asthma is distinct from, but closely linked to, allergies. Most, but not all, people with asthma also have allergies.

Asthma attack prevalence is a crude indicator of how many individuals have uncontrolled asthma and are at

A young girl is using an inhaler to facilitate breathing.
(Bikeriderlondon/Shutterstock)

risk for hospitalization. According to the Asthma and Allergy Foundation of America, each day in America, 44,000 people have asthma attacks. Asthma attack prevalence decreases with age, being most prevalent in children. Puerto Ricans have the highest asthma attack prevalence, a full 100% higher than non-Hispanic whites. The prevalence of an asthma attack is about 30% higher in non-Hispanic blacks than in non-Hispanic whites. Based on current data, Non-Hispanic blacks are the most likely to die from asthma, with an asthma death rate more than 200% higher than that of non-Hispanic whites. Women have an asthma death rate approximately 40% higher than men. Differences in male and female hormones may cause this disparity.

Asthma has been described as the fastest-growing chronic disease and a worldwide epidemic. According to Global Initiative for Asthma (GINA), an asthma research and education program, asthma accounts for about one in every 250 deaths worldwide. Many of the deaths are believed to be preventable and are caused by poor medical care.

The World Health Organization (WHO) estimates that there are 235 million people with asthma worldwide. In most countries, asthmatic cases are increasing by 20% to 50% every decade. The United States is one of the top countries for prevalence of asthma, along with England, Australia, parts of South America, and Canada. In Australia, the incidence of asthma is very high in Caucasian children but much lower in aboriginal children.

It is speculated that lifestyle factors, such as a lack of physical activity, increased obesity, and more time spent indoors, may contribute to higher rates of asthma in highly developed countries. It is also possible that environmental irritants, such as poor indoor and outdoor air quality, along with the presence of potent irritants such

as cockroach allergens, may contribute to higher rates of childhood asthma in poorer communities. Other factors that may prompt the onset of asthma include viral respiratory infections, low birth weight, and smaller-than-average air passageways in asthmatic patients.

Signs and symptoms

People with asthma may experience coughing that is often worse at night or early in the morning, making sleep difficult. Wheezing is a common symptom, creating a whistling or squeaky sound when breathing. People with asthma experience tightness in the chest region, as if their chest feels it is being compressed. Shortness of breath and the feeling of breathlessness are common symptoms. There is difficulty getting enough air into or out of the lungs, especially during exhalation. If airflow to the lungs is inadequate, a lack of sufficient oxygen to the tissues causes the body to breathe more rapidly in an attempt to get more oxygen. People with asthma often breathe more rapidly as a result.

People with asthma often have wheezing during a cold, flu, or other illness. Emotional stress may also result in asthmatic symptoms, such as coughing or wheezing from prolonged crying or laughing. Many indoor and outdoor factors can trigger or initiate typical symptoms of asthma, including allergies, viral respiratory infections, weather changes, and exercise. Medications containing aspirin also act as asthma triggers in about 10% to 20% of adults with asthma.

When allergies stimulate an asthma attack, it is known as allergic asthma. Allergic asthma is stimulated when an affected individual is physically near an allergen or irritant. Research has confirmed that allergies cause the majority of childhood asthma cases. Allergic asthma is the most common form of asthma and tends to run in families. Common allergens that may contribute to allergies and asthmatic reactions include dust mites, dust particles, animal dander, animal hair, bird feathers, mold, plant pollen, and substances found in food. Food products containing peanuts, eggs, dairy products, or seafood can cause asthma attacks in some children with allergies to these foods. Food additives, such as sulfites, can also act as asthma triggers. Synthetic (manmade) products like the latex material used in surgical gloves can also trigger asthmatic episodes in susceptible individuals. Non-allergic factors that can stimulate or aggravate asthmatic symptoms include tobacco smoke, chalk dust, talcum powder, car exhaust, and fumes from chemicals such as household cleaners. Auto pollution is a major factor in asthma prevalence.

Exercise is a common trigger for asthma in about 80% of asthmatic individuals. Some people with asthma have exercise-induced symptoms precipitated

by brisk activity such as running, especially during cold weather. Pretreatment medications, such as short-acting bronchodilators, quickly widen air passages and thus help prevent the onset of asthma while an asthmatic individual participates in physical activities. Activities that allow for frequent breaks, rather than prolonged endurance, are most suitable. Asthma does not have to be a barrier to participating in athletic activities. Many Olympic athletes have exercise-induced asthma that is controlled by medication.

Changes in the weather, such as temperature and humidity variations, can also negatively affect asthma patients. Cold climates also may exacerbate asthma, because the lungs have to work harder to warm and moisten inhaled air. People with asthma who exercise in such conditions could wear a surgical mask that can trap the warm, moist air exhaled with each breath. Viral infections of the respiratory system, which tend to increase in number during winter months, may trigger severe asthma attacks. Additionally, unclean and poorly maintained forced-air heating systems release many pollutants that further aggravate asthmatic symptoms.

Every asthma patient is unique. Because there are so many environmental conditions that affect individuals with a genetic predisposition for asthma, it is often difficult to pinpoint the primary cause of the disease in individual cases.

A person with asthma may have any combination of symptoms, which may vary from one asthma attack to another. Symptoms may exhibit a range of severity, from mildly irritating to life-threatening. They occur with varying frequency from once every few months to every day. Asthma classifications are based on symptom levels in the absence of medication. Mild intermittent asthma is defined as symptoms of wheezing, coughing, or breathing difficulty less than twice per week or less, with night symptoms twice per month or less. Mild persistent asthma is defined as symptoms of wheezing, coughing, or breathing difficulty once per day or less, but more than twice per week. Symptoms occur at night more than twice per month.

Moderate persistent asthma is defined as daily symptoms that require daily medication. Symptoms at night occur more than once per week. They may be severe enough to interfere with normal physical activity.

Severe asthma is described as ongoing, persistent symptoms with more serious asthma attacks. Symptoms may occur throughout the day, with night symptoms occurring often. In severe asthma, physical activity is likely to be limited.

All people with asthma may have severe asthma attacks. However, with appropriate treatment and

KEY TERMS

Allergen—A substance or organism foreign to the body; allergens stimulate the immune system to produce antibodies.

Allergy—A condition in which the immune system is hypersensitive to contact with allergens; an abnormal response by the immune system to contact with an allergen; a condition in which contact with an allergen produces symptoms such as inflammation of tissues and production of excess mucus in the respiratory system.

Antibody—A protein produced by the mature B cells of the immune system that attach to invading micro-organisms and target them for destruction by other immune system cells.

Antigen—A substance or organism that is foreign to the body and stimulates a response from the immune system.

Autoimmune disease—A condition in which the immune system attacks the body because it mistakes parts of it as foreign.

Bronchi—Branching tube-like structures that carry air into and out of the lungs. The walls of the bronchi contain circular muscles that can constrict (tighten up to make airways narrower) or dilate (relax to make airways wider). The bronchi divide into smaller bronchioles within the lung tissue.

Biologic—A medication that is made from a plant, animal, or micro-organism, such as bacteria.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein. It is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Genetic disease—A disease that is (partly or completely) the result of the abnormal function or expression of a gene; a disease caused by the inheritance and expression of a genetic mutation.

Histamine—A substance released by immune system cells in response to the presence of an allergen. Histamine stimulates widening of blood vessels and increased porousness of blood vessel walls so that fluid and protein leak out from the blood to surrounding tissue, causing inflammation.

Hypersensitive—Referring to a process or reaction that occurs at above-normal levels; over-reacting to a stimulus.

IgE—An antibody composed of protein; specific forms of IgE produced by cells of the immune system in response to different antigens that contact the body; a major factor that stimulates the allergic response.

Immune system—A major system of the body that produces specialized cells and substances that interact with and destroy foreign antigens that invade the body.

Inflammation—Swelling and reddening of tissue; usually caused by the immune system's response to the body's contact with an allergen.

avoidance of asthma stimulators, most people with asthma can achieve a general condition of minimal or no symptoms. People with asthma are encouraged to learn to recognize their own specific asthma stimulators and avoid them, and they are recommended to recognize their specific pattern of early warning signs that signal the start of an attack. The first signs of a mild or moderate attack may be a slight tightening of the chest, coughing or wheezing, and spitting up mucus. Severe attacks can bring on a feeling of extreme tightening of the neck and chest, making breathing increasingly difficult. People with asthma may struggle to speak or breathe. In advanced stages of severe attacks, lips and fingernails may take on a grayish or bluish tinge, indicating declining oxygen levels in the blood. Such attacks can be fatal in the absence of prompt medical attention. Fortunately, asthma symptoms are usually reversible with medication.

Diagnosis

The first stage of asthma diagnosis is from a history of asthmatic symptoms. These symptoms include periods of coughing, wheezing, shortness of breath, or chest tightness that come on suddenly in response to specific stimulants or time periods. A history of head colds that evolve into chest congestion or take more than 10 days to recover from is pertinent. Family history of asthma or allergies may also be part of the diagnosis.

A physical exam may reveal wheezing in the chest that can be heard with a stethoscope. A device called a spirometer may be used to check the function of the airways in children over five years of age and in adults. The test measures the volume of air and the speed with which it can be blown out of the lungs after a deep breath. If the airways are narrowed from inflammation and the muscles around the airways tightening up from asthma,

the results will be lower than normal. If spirometry results are normal, but asthma symptoms are present, other tests are performed. A bronchial challenge test involves inhalation of a substance such as methacholine, which causes narrowing of the airways in asthma. The effect is measured by spirometry to determine whether asthma is present. Children under five years of age usually cannot use a spirometer successfully. In such cases, asthma medications are often attempted as part of the diagnosis to determine whether they are able to alleviate the symptoms.

Allergy testing may be performed to determine whether there are specific allergens to which the individual is reactive. A device called a peak flow meter may be used every day for several weeks to measure breathing efficiency. Tests may be performed to determine the reaction of the airways to exercise. In some cases, a chest x-ray or an electrocardiogram may be used to determine whether a foreign object, other lung disease, or heart disease could be causing asthma-like symptoms. The results of the medical history, physical exam, and lung function tests are used to diagnose the severity of asthma and determine treatment.

Treatment and management

Asthma is treated by avoiding stimulating factors and by medication. There are two main types of asthma medication. Acute medications give rapid, short-term treatment but are only used when asthma symptoms require immediate relief. These medications are bronchodilators that may be inhaled and take effect within minutes to dilate the airways and allow normal breathing. Bronchodilators may be used at the beginning of an asthma attack to provide relief. They also may be used before exercise to prevent exercise-induced asthma symptoms. Long-term control medications are taken daily over long periods of time to control chronic symptoms and prevent asthma attacks. The full effect of these medications requires several weeks of use. Individuals with persistent asthma require long-term control medications.

The most effective, long-term control medication for asthma is an inhaled corticosteroid. Corticosteroids work by suppressing inflammation caused by overactive Th2 cells. They can reduce the swelling of airways and help to prevent asthma attacks from occurring. Inhaled corticosteroids are preferred for treatment of all levels of persistent asthma. In some cases, steroid tablets or liquid medications are used temporarily to control asthma. Other types of asthma medications inhibit the inflammatory mediators released in the asthma response. Some of these long-term control medications may be used in combination with inhaled corticosteroids to treat moderate persistent and severe persistent asthma. Long-term control medications are used in a preventative manner and

QUESTIONS TO ASK YOUR DOCTOR

- What are the causes of asthma?
- Is stress likely to increase the frequency and severity of my asthma attacks?
- Are there lifestyle changes I can make to reduce the frequency and severity of my asthma attacks?
- Is my asthma condition likely to improve or get worse over time?
- Are there any new treatments I should try?

will not stop an asthma attack in progress. Many people with asthma require both a short-acting bronchodilator to use when symptoms worsen and a long-term daily asthma control medication to treat ongoing inflammation.

Uncontrolled asthma during pregnancy can be very dangerous. Lowered oxygen levels to the fetus may cause damage. Many asthma treatments are considered safe to use during pregnancy. Older adults may need adjustments in asthma treatment because of other present diseases or conditions. Some medications, such as beta-blockers used for hypertension, aspirin, and nonsteroidal anti-inflammatory drugs such as ibuprofen, can interfere with some asthma medications or cause asthma attacks. The use of corticosteroids may also adversely affect bone density in adults.

People with asthma can monitor the function of their respiratory system with the aid of peak flow meters and spirometers. These devices measure the amount of air exhaled with each breath. They are used to regularly monitor the severity of asthma symptoms and to evaluate and manage treatment procedures for individual patients. Maintaining control over asthma symptoms and keeping a healthy lifestyle are key components of asthma treatment.

Emergency care may become necessary during a severe asthma attack. Emergency care takes place in a hospital setting and may include treatment with high levels of bronchodilators and corticosteroids, additional medications, and oxygen administration in an attempt to restore normal respiratory activity. Delayed access to emergency treatment can lead to complete respiratory failure, where the patient simply stops breathing and cannot be revived.

Allergen Desensitization

Allergen immunotherapy, also called desensitization, decreases symptoms in people with allergies to

environmental allergens like plants and animals. During these treatments, people with asthma are given shots of increasing amounts of the allergen. This treatment can take three to five years but can significantly reduce the severity of asthma and lower the amount of medication required. The benefits of this treatment can last for seven to 12 years after it is stopped. This treatment seems to improve the Th2 response.

Biologics

There are a number of biologic medications (biologics) that target specific aspects of the overactive immune response caused by Th2 cells and help treat severe asthma. Some biologics, such as Omalizumab, decrease the amount of IgE and make cells less sensitive to stimulation by allergens. Other biologics, including Mepolizumab, Reslizumab, Benralizumab, and Dupilumab, reduce the activity of proteins produced by the Th2 cells, which decreases the body's response to allergens. Still other biologics, like Tezepelumab, decrease the amounts of certain proteins that stimulate Th2 cells.

Prognosis

There is currently no cure for asthma, but proper treatment and management have dramatically improved the quality of life for individuals with asthma. When medication is used properly, the prognosis for most people with asthma is excellent. An improvement in environmental conditions can reduce the number and severity of asthma attacks and improve the prognosis. Such improvement is also believed to affect the overall prognosis for a society, simply by decreasing the number of individuals who are sensitized to environmental triggers.

Astrocytoma

Definition

Astrocytoma is a tumor that arises from astrocytes, star-shaped cells that play a supportive role in the brain.

Description

The brain acts as a computer that controls all of the functions of the body. It stores information, regulates behavior, and sends instructions to the rest of the body. Because of the brain's importance, cancers in the brain can affect many of the body's functions. The location of a tumor within the brain determines which effects it will have. Astrocytomas may occur in the cerebrum, the cerebellum, or the brainstem. The cerebrum is the site of thought and language. The cerebellum is the area responsible for movement and muscle co-ordination. The brainstem is the location that regulates critical activities like breathing and heartbeat. Astrocytomas in children are most commonly located in the cerebellum. Astrocytomas in adults usually develop in the cerebrum.

Astrocytomas rarely metastasize (spread) outside the brain to other parts of the body. However, they may grow and spread within the brain. Because there is no extra room in the skull, the presence of a brain tumor causes an increase in intracranial (within the skull) pressure. This leads to headaches. Furthermore, normal brain function is affected possibly by compressing delicate brain tissue.

Astrocytomas are a type of glioma. The glioma classification identifies a tumor of glial cells that are specialized cells giving physical support and electrical insulation between neurons. They are sometimes called gliomas, anaplastic astrocytomas, or glioblastoma multiforme. Oligoastrocytomas are a type of mixed glioma similar to astrocytomas. They are usually low grade tumors containing cells that originate from oligodendrocytes as well as astrocytes. Grading is an estimate of the tumor's malignancy and aggressiveness; lower-grade tumors require less drastic therapy than high-grade tumors.

This MRI image of the brain shows a large, rounded mass (purple), which is a tumor. (Living Art Enterprises/Science Source)

Genetic profile

Researchers are still learning about the many possible genetic and hereditary causes of astrocytomas. They have made some progress. Recent findings include the connection between neurofibromatosis type 1 and astrocytoma in the visual pathway. Neurofibromatosis type 1 is an inherited condition caused by changes to the *NF1* gene. Children with this condition tend to develop a type of astrocytoma in the visual pathway. Inherited mutations of the phosphatase and tension homolog, or *PTEN*, gene are found in many astrocytomas. The *PTEN* gene is involved in making a protein that is found in nearly all of the body's tissues. In addition, mutation of the "deleted in malignant brain tumors 1" (*DMBT1*) gene likely is involved in formation of astrocytomas and glioblastoma multiforme tumors. Presence of a certain alternative type of the peroxisome proliferator-activated receptor gamma (*PPARG*) gene has been associated with a type of glioma called glioma 1 (GLM1). The *PPARG* gene provides coding for an important protein. Other mutations associated with astrocytomas include alterations in the B-raf proto-oncogene (*BRAF*) gene and that can lead to pilocytic astrocytoma or low-grade gliomas.

Demographics

Astrocytoma occurs slightly more often in boys and men than in girls and women. It is also slightly more common in Caucasians than in those of African or Asian descent. Although it affects both adults and children,

children usually develop a less serious form with a better prognosis. The total incidence of all types of brain cancer, including astrocytomas, is approximately 13 people out of every 100,000.

Signs and symptoms

The cause of astrocytoma is not known. Brain cancer may occasionally be caused by previous radiation treatments. However, x-rays are not believed to play a role. Some studies suggest that brain tumors may occur more frequently in people who have occupational exposure to certain chemicals, including some pesticides, formaldehyde, vinyl chloride, phenols, acrylonitrile, N-nitroso compounds, polycyclic aromatic hydrocarbons, lubricating oils, and organic solvents. The greatest risk is associated with exposure before birth or during infancy.

There is a slightly higher incidence of astrocytoma in the siblings and parents of people with this tumor. However, only one type of astrocytoma is known to have a genetic cause. The rare subependymal giant cell astrocytoma occurs in conjunction with tuberous sclerosis, a hereditary disorder.

A wide variety of symptoms develop as a result of astrocytoma including the following:

- headache
- nausea and vomiting
- neck stiffness or pain
- dizziness
- seizures
- unsteadiness in walking or unusual gait
- lack of coordination, decreased muscle control
- visual problems such as blurring, double vision, or loss of peripheral vision
- weakness in arms or legs
- speech impairment
- altered behavior
- loss of appetite

Because there are several different types of astrocytoma, not all patients will show the same symptoms. The location of the tumor within the brain will determine which symptoms a patient will experience. Because the tumor causes an increase in intracranial pressure, most people with astrocytoma will develop headaches and nausea and vomiting.

Diagnosis

In the first stage of diagnosis, the doctor will take a history of symptoms and perform a basic neurological exam. Diagnosis will also include an eye exam and tests

of vision, balance, coordination and mental status. The doctor will then require a computerized tomography (CT) scan and magnetic resonance imaging (MRI) of the patient's brain. During a CT scan, x-rays of the patient's brain are taken from many different directions. These are combined by a computer, producing a cross-sectional image of the brain. For an MRI, the patient relaxes in a tunnel-like instrument while the brain is subjected to changes of magnetic field. An image is produced based on the behavior of the brain's water molecules in response to the magnetic fields. A special dye may be injected into a vein before these scans to provide contrast and make tumors easier to identify.

If a tumor is found, it will be necessary for a neurosurgeon to perform a biopsy on it. This simply involves the removal of a small amount of tumor tissue, which is then sent to a neuropathologist for examination and staging. The biopsy may take place before surgical removal of the tumor or the sample may be taken during surgery. Staging of the tumor sample is a method of classification that helps the doctor to determine the severity of the astrocytoma and to decide on the best treatment options. The neuropathologist stages the tumor by looking for atypical cells, the growth of new blood vessels, and indicators of cell division called mitotic figures. The diagnosis, staging, and classification of an astrocytoma often include molecular markers as well. These are identified genetic associations with tumors, which help doctors better target treatment.

Treatment and management

Treatment of astrocytoma often involves a neurosurgeon to remove the tumor, a neuropathologist to examine the tumor sample, and an oncologist to monitor the patient's health and coordinate radiation therapy and chemotherapy if necessary. Nurses and radiation therapists also play a role. After treatment, the patient may be followed up by a neurologist to monitor the patient for signs that the tumor has grown or recurred. There are several different systems for staging astrocytomas. The World Health Organization (WHO) system is the most common. It has four grades of increasing severity based on the appearance of the astrocytoma cells. Other methods of staging correspond fairly closely to the WHO system. Grades I and II are sometimes grouped together and referred to as low-grade astrocytomas. Over time, tumors may progress from a low-grade form with a relatively good prognosis to a higher-grade form and poorer prognosis. Additionally, tumors may recur at a higher grade.

Grade I Pilocytic Astrocytoma

This is also sometimes referred to as juvenile astrocytoma because it occurs more frequently in

KEY TERMS

Anaplastic—Undifferentiated, appearing to have an immature cell type.

Biopsy—A sample of tissue taken from the tumor.

Glioma—A tumor of the brain's glial cells.

Primary tumor—An original tumor, not a metastatic tumor resulting from cancer's spread.

children than adults. Under a microscope, the astrocytes, known as pilocytes, are thin and elongated. They are accompanied by Rosenthal fibers. The tumor mass does not invade surrounding tissues and is sometimes enclosed in a cyst. In children, pilocytic astrocytoma often occurs in the cerebellum, but may also occur in the cerebrum.

Treatment of this grade depends on the patient's age and the location of the tumor. Surgery is the preferred treatment for this type of astrocytoma. The surgical procedure is known as a craniotomy. An incision is made in the skin and an opening is made in the skull. After the tumor is removed, the bone is normally replaced and the incision closed. The neurosurgeon may also insert a shunt (drainage system) to relieve intracranial pressure. This involves inserting a catheter into a cavity inside the brain called a ventricle, then threading the other end under the skin to a drainage area where the fluid is absorbed.

If the tumor can be completely surgically removed, the patient may not need further therapy and may be monitored only for recurrence. If the tumor cannot be completely removed, patients may be given chemotherapy as well. If the tumor is not completely resected or if it continues to grow after chemotherapy, radiation therapy may be necessary. Radiation therapy is not normally given to children under the age of three, because it can cause permanent damage to the child's healthy brain tissue. Radiation treatment may cause swelling in the brain. Steroids may be prescribed to reduce the swelling.

The best indicator for prognosis is complete removal of the tumor. With complete tumor removal, 80% of patients are alive 10 years later. Location of the tumor in the cerebellum also suggests a better prognosis than other locations.

Grade II Low-Grade Diffuse Astrocytoma

These astrocytomas spread out and invade surrounding brain tissues but grow very slowly. Under the

microscope, fibrous structures are present. Grade II astrocytomas may occur anywhere in the brain, in the cerebellum and brain stem, or in the cerebrum, including the optic pathways. Genetic studies indicate that mutations of the tumor suppressor gene *p53* occur frequently in these tumors.

Surgical removal of the tumor is the first choice for treatment, but it may not be possible due to the tumor's location. Surgery is usually followed by radiation. Patients under 35 years of age have a better prognosis than older patients. In older patients, low-grade tumors progress to higher grades more rapidly. Overall median survival is four to five years.

Pleomorphic xanthoastrocytoma, a tumor originating in cells of a mixture of glial and neuronal origin, is often considered a grade II astrocytoma. It is relatively benign and treated only with surgery.

Grade III Anaplastic Astrocytoma

Anaplastic astrocytoma occurs most frequently in people aged 50 to 60. The term "anaplastic" means that the cells are not differentiated. They have the appearance of immature cells and cannot perform their proper functions. Researchers believe this is due to a gradual accumulation of genetic alterations in these cells. These tumor cells invade surrounding healthy brain tissue.

Anaplastic astrocytomas may be inoperable because of their location and their infiltration into normal tissue. When this occurs, radiation therapy is recommended. Chemotherapy may include various combinations of alkylating agents and other drugs, including carmustine, cisplatin, lomustine, procarbazine and vincristine. These tumors tend to recur more frequently than grade I and II tumors. Following treatment, median survival is 12 to 18 months. The five-year survival rate for these patients is approximately 10% to 35%.

Grade IV Glioblastoma Multiforme

Glioblastoma Multiforme (GBM) is the most common primary brain tumor in adults. These tumors aggressively invade adjacent tissue and may even spread throughout the central nervous system. They frequently occur in the frontal lobes of the cerebrum. Tumor biopsies may show large areas of necrosis, or dead cells, surrounded by areas of rampant growth. There may also be a mixture of cell types within the biopsy. Genetic studies show that a number of different types of mutations can take place in genes for tumor suppressor *p53* and other proteins that play a role in controlling the normal growth of cells.

Often GBM cannot be entirely surgically removed because it affects large areas of the brain. Radiation

therapy will be given regardless of whether surgery is possible, except to very young children. Conventional radiation may be performed, but more specialized types may also be used. One of these specialized types, stereotactic radiosurgery, uses imaging and a computer to treat the tumor very precisely. Another, interstitial radiation, delivers radiation by placing radioactive material directly on the tumor. Chemotherapy will follow radiation; it may include carmustine, lomustine, procarbazine, and vincristine.

GBM is most common in patients over 50 years of age and rarely occurs in patients under 30. Increasing age is associated with a poorer prognosis. Median survival is 9 to 11 months following treatment. Fewer than 5% of patients are alive five years later. Because of the poor prognosis of GBM, it is treated more aggressively than low-grade astrocytomas. Many clinical trials take place to test new treatments.

Alternative and complementary therapies

No specific alternative therapies have been noted as effective for this particular type of brain cancer, but patients interested in pursuing complementary therapies should discuss the idea with their doctor. A doctor may be able to provide information about how helpful certain techniques can be at relieving symptoms or improving quality of life. An important concern is whether they may interfere with conventional treatment.

Patients may experience unpleasant side effects from treatment. Patients should discuss any side effects they experience with their doctors. Occasionally an effect may be unexpected or dangerous and dosages may need to be adjusted. Doctors can help alleviate nausea with anti-nausea medications and may prescribe antidepressants to help the patient deal with the cancer on a psychological level. Joining support groups will also help patients deal with the psychological effects of treatment. Cancer survivors can help provide encouragement and offer advice for coping with cancer on a day-to-day basis.

Clinical trials are an important treatment possibility, especially for patients who have tumors that are inoperable or who do not respond well to treatment. Participation in clinical trials also gives patients an opportunity to make contributions to the search to find a cure for their cancer. A wide variety of clinical trials are available, particularly for the higher-grade astrocytomas. Trials for higher-grade astrocytomas may test new drugs, new combinations of drugs, drug implants, and higher doses of drugs, possibly in combination with different methods of radiation therapy. Some studies may examine the use

QUESTIONS TO ASK THE DOCTOR

- Where inside my brain is the cancer located and where will it spread?
- What types of treatment are recommended?
- What are the possible side effects of this treatment?
- How can the side effects be minimized?
- Am I eligible for any clinical trials?
- Are there any alternatives to this treatment?
- What are the chances that the cancer will return?
- Will this cause any disabilities?
- How will this affect my daily life?

of gene therapy. Others analyze immune therapy, including vaccines.

Trials for lower-grade astrocytomas focus on finding chemotherapy that causes fewer side effects. Some studies may also feature new combinations of drugs while others may attempt to treat the tumor by using lower dosages of drugs spread out over a longer period of time.

Currently, scientists do not know what causes most brain cancers. There may be a slight genetic predisposition as family members of astrocytoma patients have a slightly increased incidence of the disease. Clinical studies show that a large number of genetic alterations take place in the higher grade astrocytomas. Although this helps to explain what is going wrong in the cells, it does not explain what is causing these genetic mutations to take place or how to prevent them.

While it is known that ionizing radiation can cause brain tumors, most people are not exposed to this type of radiation unless they are being treated for cancer. Ongoing studies are examining the long-term risks of other types of radiation, but neither x-rays, electromagnetic fields, nor cell phones appear to increase the likelihood of brain cancers.

Although evidence is not yet conclusive, some studies suggest that brain tumors may be caused by environmental exposure to certain organic chemicals. Exposure is most harmful to the developing fetus and infants, so pregnant women may wish to consider whether they have any occupational exposure to organic chemicals. Parents of infants should be aware of pesticides and any other potentially harmful chemical their child could come into contact with.

Prognosis

Children who develop astrocytoma should be monitored regularly by their physicians to ensure that the tumor does not recur. A follow-up schedule should be discussed with the doctor. The child may be examined twice a year initially and then tested annually afterwards. In addition to the possibility of recurrence, other health problems from treatment may arise in the child. The child may have lower levels of growth hormone or thyroid hormone. They may experience delayed growth as a result of radiation. There may also be intellectual, learning, or physical disabilities that can be detected during follow-up. Parents can then arrange for rehabilitation or special needs education for their child.

Adults may also experience permanent negative effects as a result of their treatment. Radiation damage to healthy tissue may occasionally cause delayed effects such as decreased intellect, impaired memory, changes in personality, and confusion. These types of side effects should be reported to a health professional. The patient can be referred to rehabilitation specialists who can help with regaining abilities.

Ataxia-Telangiectasia

Definition

Ataxia-Telangiectasia (A-T) is a rare, genetic neurological disorder that progressively affects various systems in the body. Children affected with A-T appear normal at birth; however, the first signs of the disease—usually a lack of balance and slurred speech—often appear between one and two years of age.

Description

The onset of cerebellar ataxia (unsteadiness and lack of coordination) marks the beginning of progressive degeneration of the cerebellum, the part of the brain responsible for motor control (movement). This degeneration gradually leads to a general lack of muscle control and eventually confines the patient to a wheelchair. Children with A-T become unable to feed or dress themselves without assistance. Because of the worsening ataxia, children with A-T lose their ability to write, and speech also becomes slowed and slurred. Even reading eventually becomes impossible, as eye movements become difficult to control.

Soon after the onset of the ataxia, an individual usually exhibits another symptom of the disease—telangiectases, or tiny red spider veins (dilated blood vessels). These telangiectases appear in the corners of the eyes—giving the eyes a bloodshot appearance—or on the surfaces of the ears and cheeks exposed to sunlight.

In about 70% of children with A-T, another symptom of the disease is present: an immune system deficiency that usually leads to recurrent respiratory infections. In many patients, these infections can become life threatening. Because of deficient levels of IgA and IgE immunoglobulins—the natural infection-fighting agents in the blood—children with A-T are highly susceptible to lung infections that are resistant to the standard antibiotic treatment. For these patients, the combination of a weakened immune system and progressive ataxia can ultimately lead to pneumonia as a cause of death.

Children with A-T tend to develop malignancies of the blood circulatory system almost 1,000 times more frequently than the general population. Lymphomas (malignant tumors of lymphoid tissues) and leukemias (abnormal overgrowth of white blood cells, causing tumor cells to grow) are particularly common types of cancer, although the risk of developing most types of cancer is high in those with A-T. Another characteristic of the disease is an increased sensitivity to ionizing radiation (high-energy radiation such as x-rays), which means that

patients with A-T frequently cannot tolerate the radiation treatments often given to cancer patients.

Genetic profile

Ataxia-Telangiectasia is called a recessive genetic disorder because parents do not exhibit symptoms; however, each parent carries a recessive (unexpressed) gene that may cause A-T in offspring. The genetic path of A-T is therefore impossible to predict. The recessive gene may lie dormant for generations until two people with the defective gene have children. When two such A-T carriers have a child together, there is a 25% risk of having a child with A-T. Every healthy sibling of a child with A-T has a 50% risk of being a carrier, like his or her parents.

The A-T gene (called *ATM*, or A-T Mutated) was discovered by Tel Aviv researchers in 1995. The ATM protein is thought to prevent damaged DNA from being reproduced. However, the cells of patients with A-T lack the ATM protein, although the cells of those with the mild form of the disorder contain small amounts of it. It is thought that ATM is involved in sending messages to several other regulating proteins in the body. The absence of ATM severely disrupts the transmission of these messages, thereby affecting many different systems of the body.

Scientists have discovered that the *ATM* gene is often found with the *p53* gene, which is defective in the majority of cancerous tumors. Tumor biologists, therefore, view A-T as one of the most explicit human models for studying inherited cancer susceptibility. In children who have A-T, the defective *A-T* gene blocks the normal development of the thymus, the organ most important for the development of the immune response. Understanding how immunodeficiencies develop in children with A-T may have relevance to research on other immunodeficiency disorders.

Demographics

Both males and females are equally affected by A-T. Epidemiologists estimate the frequency of A-T as between 1 in 40,000 and 1 in 100,000 live births worldwide. However, it is believed that many children with A-T, particularly those who die at a young age, are never properly diagnosed. Thus, the disease may occur much more often than reported.

According to the National Cancer Institute (NCI), about 1% (2.5 million) of the American population carry a copy of the defective *A-T* gene. According to some researchers, these gene carriers may also have an increased sensitivity to ionizing radiation and have a

significantly higher risk of developing cancer—particularly breast cancer in female carriers.

Signs and symptoms

Although there is much variability in A-T symptoms among patients, the signs of A-T almost always include the appearance of ataxia between the ages of two and five. Other, less consistent symptoms may include neurological symptoms, cutaneous (skin) symptoms, and a variety of other conditions.

Neurological

Neurological symptoms of A-T include:

- progressive cerebellar ataxia (although ataxia may appear static between the ages of two and five)
- cerebellar dysarthria (slurred speech)
- difficulty swallowing, causing choking and drooling
- progressive apraxia (lack of control) of eye movements
- muscle weakness and poor reflexes
- initially normal intelligence, sometimes with later regression to mildly retarded range

Cutaneous

Cutaneous symptoms include:

- progressive telangiectases of the eye and skin develop between two to ten years of age
- atopic dermatitis (itchy skin)
- café au lait spots (pale brown areas of skin)
- cutaneous atrophy (wasting away)
- hypo- and hyperpigmentation (under-pigmented and over-pigmented areas of skin)
- loss of skin elasticity
- nummular eczema (coin-shaped inflammatory skin condition)

Other symptoms

Other manifestations of A-T include:

- susceptibility to neoplasms (tumors or growths)
- endocrine abnormalities
- tendency to develop insulin-resistant diabetes in adolescence
- recurrent sinopulmonary infection (involving the sinuses and the airways of the lungs)
- characteristic loss of facial muscle tone
- absence or dysplasia (abnormal development of tissue) of thymus gland
- jerky, involuntary movements
- slowed growth

- prematurely graying hair

Diagnosis

For a doctor who is familiar with A-T, the diagnosis can usually be made on purely clinical grounds and often on inspection. But because most physicians have never seen a case of A-T, misdiagnoses are likely to occur. For example, physicians examining ataxic children frequently rule out A-T if telangiectases are not observed. However, telangiectases often do not appear until the age of six and sometimes appear at a much older age. In addition, a history of recurrent sinopulmonary infections might increase suspicion of A-T, but about 30% of patients with A-T exhibit no immune system deficiencies.

The most common early misdiagnosis is that of static encephalopathy—a brain dysfunction, or ataxic cerebral palsy—paralysis due to a birth defect. Ataxia involving the trunk and gait is almost always the presenting symptom of A-T. And although this ataxia is slowly and steadily progressive, it may be compensated for—and masked—by the normal development of motor skills between the ages of two and five. Thus, until the progression of the disease becomes apparent, clinical diagnosis may be imprecise or inaccurate unless the patient has an affected sibling.

Once disease progression becomes apparent, Friedreich ataxia (a degenerative disease of the spinal cord) becomes the most common misdiagnosis. However, Friedreich ataxia usually has a later onset. In addition, the spinal signs involving posterior and lateral columns along the positive Romberg's sign (inability to maintain balance when the eyes are shut and feet are close together) distinguish this type of spinal ataxia from the cerebellar ataxia of A-T.

Distinguishing A-T from other disorders (differential diagnosis) is ultimately made on the basis of laboratory tests. The most consistent laboratory marker of A-T is an elevated level of serum alpha-fetoprotein (a protein that stimulates the production of antibodies) after the age of two years. Prenatal diagnosis is possible through the measurement of alpha-fetoprotein levels in amniotic fluid and the documentation of increased spontaneous chromosomal breakage of amniotic cell DNA. Diagnostic support may also be offered by a finding of low serum IgA, IgG, and/or IgE. However, these immune system findings vary from patient to patient and are not abnormal in all individuals.

The presence of spontaneous chromosome breaks and rearrangements in lymphocytes in vitro (test tube) and in cultured skin fibroblasts (cells from which connective tissue is made) is also an important laboratory marker of A-T. And finally, reduced survival of lymphocyte

KEY TERMS

Alpha-fetoprotein (AFP)—A chemical substance produced by the fetus and found in the fetal circulation. AFP is also found in abnormally high concentrations in most patients with primary liver cancer.

Atrophy—Wasting away of normal tissue or an organ due to degeneration of the cells.

Cerebellar ataxia—Unsteadiness and lack of coordination caused by a progressive degeneration of the part of the brain known as the cerebellum.

Dysarthria—Slurred speech.

Dysplasia—The abnormal growth or development of a tissue or organ.

Immunoglobulin—A protein molecule formed by mature B cells in response to foreign proteins in the body; the building blocks for antibodies.

Ionizing radiation—High-energy radiation such as that produced by x-rays.

Leukemia—Cancer of the blood-forming organs, which results in an overproduction of white blood cells.

Lymphoma—A malignant tumor of the lymph nodes.

Recessive gene—A type of gene that is not expressed as a trait unless inherited by both parents.

Telangiectasis—Very small arteriovenous malformations, or connections between the arteries and veins. The result is small red spots on the skin known as “spider veins.”

(cells present in the blood and lymphatic tissues) and fibroblast cultures, after exposure to ionizing radiation, will confirm a diagnosis of A-T, although this technique is performed in specialized laboratories and is not routinely available to physicians.

When the mutated A-T gene (ATM) has been identified by researchers, it is possible to confirm a diagnosis by screening the patient's DNA for mutations. However, in most cases the large size of the ATM gene and the large number of possible mutations in patients with A-T seriously limit the usefulness of mutation analysis as a diagnostic tool or method of carrier identification.

Treatment and management

There is no specific treatment for A-T because gene therapy has not become an option. Also, the disease is

QUESTIONS TO ASK YOUR DOCTOR

- Are my child's symptoms likely to be caused by some condition other than Ataxia-Telangiectasia?
- What course of action is available for dealing with this condition?
- Based on the signs and symptoms of the condition at this point, what is the prognosis for the disorder in my child?

usually not diagnosed until the individual has developed health problems. Treatment is therefore focused on the observed conditions, especially if neoplasms are present. However, radiation therapy must be minimized to avoid inducing further chromosomal damage and tumor growth.

Supportive therapy is available to reduce the symptoms of drooling, twitching, and ataxia, but individual responses to specific medications vary. The use of sunscreens to retard skin changes due to premature aging can be helpful. In addition, early use of pulmonary physiotherapy, physical therapy, and speech therapy is also important to minimize muscle contractures (shortening or tightening of muscles).

Although its use has not been formally tested, some researchers recommend the use of antioxidants (such as vitamin E) in patients with A-T. Antioxidants help to reduce oxidative damage to cells.

Clinical trials

Clinical trials for the treatment or prevention of A-T are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2015, NIH reported 18 ongoing studies.

A few examples include:

- The evaluation of antibody responses to a pneumococcal vaccine for the treatment of A-T. (NCT00656409)
- A study on the treatment of A-T in children with cancer. (NCT00187057)
- The evaluation of whether Baclofen, a medicine that is often used for the treatment of abnormal stiffness, might also be useful to treat some of the neurologic problems caused by A-T. (NCT00640003)

Clinical trial information is constantly updated by NIH and the most recent information on A-T trials

can be found at <http://clinicaltrials.gov/search/open/condition=%22Ataxia+Telangiectasia%22>

Prognosis

A-T is an incurable disease. Most children with A-T depend on wheelchairs by the age of ten because of a lack of muscle control. Children with A-T usually die from respiratory failure or cancer by their teens or early twenties. However, some patients with A-T may live into their forties, although this is extremely rare.

Attention deficit hyperactivity disorder

Definition

Attention deficit hyperactivity disorder (ADHD) is a neurological disorder that presents in various forms, with no two ADHD disorders having exactly the same characteristics. ADHD is classified as a disruptive behavior disorder characterized by ongoing difficulty with attention span, hyperactivity, and/or impulsivity. These difficulties occur more frequently and severely than is typical for individuals in the same stage of development.

Description

ADHD is a neurological condition, frequently familial, that affects specific types of brain functioning. The term ADHD is further divided into presentations (subcategories) that describe the type of ADHD. The three

Students diagnosed with attention deficit hyperactivity disorder find it difficult to concentrate for long periods of time. (Suzanne Tucker/Shutterstock)

presentations recognized by the scientific community are ADHD inattentive type, ADHD impulsive-hyperactive type, and ADHD combined type. Some individuals, including many professionals, still refer to the condition as ADD (attention deficit disorder). However, this term is no longer in widespread use. For individuals who have been diagnosed with ADD in the past, the corresponding current terminology is most likely to be predominantly ADHD, inattentive type.

It is possible to meet the accepted diagnostic criteria for ADHD without displaying any symptoms of hyperactivity or impulsivity. Each ADHD individual will display a unique combination of symptoms. They will not necessarily have all of the symptoms associated with ADHD. Furthermore, the levels of severity or impairment vary from individual to individual. There are mild forms of ADHD in addition to the severe forms that result in significant impairment. Symptoms of ADHD usually begin before age seven. In later life, these symptoms can cause problems in school, work, family life, and relationships. ADHD can be managed through behavioral or medical interventions or a combination of the two. Despite public controversy over the legitimacy of the disorder's existence, the National Institutes of Health (NIH), the Surgeon General of the United States, and the international community of clinical researchers and physicians have affirmed that ADHD is a valid disorder that may result in severe, lifelong consequences if left untreated. The U.S. Senate designated September 7, 2004, as National Attention Deficit Disorder Awareness Day.

Genetic profile

The exact cause of ADHD is unknown, although abnormal neurotransmitter levels, genetics, and complications occurring around the time of birth have been implicated. According to the National Resource Center on ADHD, heredity makes the largest contribution to the prevalence of ADHD in the population, and evidence for heritability comes from family, twin, and adoption studies. Genetic influences are estimated to account for 70% to 80% of the risk. Inheritance is an important risk factor as ADHD occurs frequently in families. Between 10% and 35% of children diagnosed with ADHD have a first-degree relative with ADHD. Approximately 50% of parents who have ADHD have a child with the disorder. ADHD is significantly more likely to be present in an identical (monozygotic) twin than in a fraternal (dizygotic) twin.

Genome-wide association studies (GWASs) have found that ADHD is associated with many rare and common genetic variants. As of 2021, at least 21 gene variants have been associated with ADHD risk. Among these are *FOXP2*, which has been implicated in speech

and language disorders as well as adult ADHD, and *DUSP6*, which governs the balance of neurotransmitters by regulating dopamine levels in the synapses, the gaps between neurons across which impulses are conveyed by a neurotransmitter. Because symptoms of ADHD respond well to treatment with stimulants that increase the availability of the neurotransmitter dopamine, the dopamine hypothesis has gained acceptance. It suggests that ADHD is due to inadequate availability of dopamine in the central nervous system. Dopamine plays a key role in initiating focused movement, increasing motivation and alertness, and preventing sleepiness in response to boredom. Multiple genes have been implicated in ADHD, including genes affecting dopamine usage by the brain.

The GWAS also demonstrated that much of the heritability of ADHD is due to the polygenic effects of many common variants, each having very small effects. In addition, some genetic syndromes, such as the 15q11.2 BP1-BP2 and fragile X, Turner syndrome, tuberous sclerosis, neurofibromatosis, Klinefelter syndrome, and Williams syndrome have ADHD as a symptom.

The male-to-female ratio is 8:1. Despite the strong genetic linkage, research also suggests that non-genetic factors may play a role in ADHD. Hyperactivity and inattention are more common in children who have had exposure to toxins such as lead, alcohol, or cigarette smoke, or episodes of fetal oxygen deprivation during complications of pregnancy. These factors may adversely affect dopamine-rich areas of the brain.

In addition to dopamine, research has shown that glucose usage may be involved in ADHD. Brain-imaging studies, using magnetic resonance imaging (MRI), have demonstrated differences between the brains of children with and without ADHD. A link has been established between an individual's ability to pay continued attention and the brain's use of glucose as a fuel. In adults with ADHD, the brain areas that control attention span may use less glucose and be less active, suggesting that a lower level of activity in this part of the brain may cause the inattention symptoms associated with ADHD.

By 2002, the NIMH Child Psychiatry Branch concluded a decade-long controlled study that demonstrated ADHD children having 3% to 4% smaller brain volumes in multiple critical brain regions affecting the types of behaviors associated with ADHD. The study also demonstrated that ADHD children receiving medication had developed a volume of white matter that was the same as in normal children. Individuals who had ADHD, but were never medicated, had an abnormally small volume of white matter.

Demographics

ADHD is the most commonly diagnosed behavioral disorder of childhood, affecting an estimated 8% to 12% of school-aged children. Males are considered up to eight times more likely to have ADHD than females, although the difference between the numbers of males and females may be due in part to males having a higher rate of hyperactivity symptoms that are easier to detect and diagnose. ADHD often occurs in conjunction with other problems, such as depressive and anxiety disorders, conduct disorders, drug abuse, and antisocial behaviors. Among children ages three to 10, The 2016-2018 National Health Interview Survey found that non-Hispanic black children (16.9%) were more likely than white (14.7%) or Hispanic children (11.9%) to have been diagnosed with ADHD. Children with untreated ADHD have increased rates of injury and co-morbid psychiatric disorders. Approximately 70% to 80% of children with ADHD continue to exhibit significant symptoms into adolescence and adulthood.

An estimated 2% to 6% of adolescents and 2% to 4% of adults have ADHD. Adults who had untreated ADHD in childhood have more severe symptoms and adverse risk factors later in life. Adverse factors both influence the expression of ADHD and increase the risk for associated disorders reducing overall adjustment throughout life. ADHD is considered a lifelong disorder that requires accurate diagnosis and appropriate treatment.

Signs and symptoms

Symptoms of ADHD often become apparent by age seven, but many adults remain undiagnosed. The three presentations of ADHD recognized by the scientific community include a predominantly hyperactive-impulsive type that does not display significant symptoms of inattention, a predominantly inattentive type that does not display significant symptoms of hyperactive-impulsive behavior, and a combined type that displays both the inattentive and hyperactive-impulsive symptoms associated with ADHD. The predominantly inattentive type is sometimes still referred to as ADD, but this is an outdated term for the disorder.

Symptoms of inattention tend to persist through childhood into adulthood. The symptoms of inattention may include difficulty in observing details, easy distractibility, inability to concentrate, procrastination of tasks requiring sustained mental effort, frequent careless mistakes, disorganization, difficulty maintaining conversations, and difficulty completing appointed tasks. The symptoms of hyperactivity and impulsivity are nearly always present before the seventh year and tend to diminish with age. Hyperactivity symptoms may include

restlessness, excessive verbosity, and frequent inappropriate social interactions. Hyperactive behavior is often associated with the development of other disruptive behavioral disorders. It has been proposed that the impulsivity and inattention associated with ADHD may interfere with social learning in a way that predisposes the individual to the development of these disorders.

While many of these symptoms may sometimes occur in other children, those with ADHD experience these behaviors more intensely and across several settings. Both children and adults with ADHD may experience these symptoms to a degree that interferes with normal functioning. Some individuals with moderate to severe ADHD may also experience periods of anxiety or depression. Individuals whose predominant symptom is inattention are most prone to depression. It follows that ADHD rarely occurs alone. It has been demonstrated that many people with ADHD also are subject to one or more comorbid (co-occurring) conditions such as depression, anxiety disorders, learning disabilities, or substance abuse disorders. Many conditions may have symptoms similar to, and be mistaken for, ADHD. It is critical that comorbid disorders be diagnosed and treated, so that efforts to treat the ADHD will succeed. When ADHD symptoms are present as secondary to another psychiatric disorder, the individual may be incorrectly treated for ADHD. However, when ADHD is the primary disorder, treating it often eliminates or ameliorates other dysfunctions.

There are many ADHD websites available to the public. Many offer various questionnaires and descriptions of symptoms on the subject of ADHD. These websites are not standardized or scientifically validated and should never be used to diagnose ADHD. A valid diagnosis can only be provided by a qualified, licensed professional.

Diagnosis

Well-established and research-validated clinical guidelines for the diagnosis of ADHD are provided in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V). The DSM-V's criteria for diagnosis include multiple symptoms of inattention or hyperactivity-impulsivity that persist for at least six months across multiple settings such as school, work, or home. These symptoms must exist to a degree that is inconsistent with other individuals at the same developmental level. Some of the hyperactive-impulsive or inattentive symptoms must have been present before the age of twelve years. The symptoms must not occur exclusively during the course of another developmental disorder, schizophrenia, or psychotic disorder. Furthermore, the symptoms should not be diagnosed by

the description of any other mental disorder. Although fidgeting and inattentiveness are common childhood behaviors, the DSM-V criteria indicate a diagnosis of ADHD for children in whom such behavior occurs so frequently that it produces continuing, pervasive dysfunction. A diagnostic evaluation requires histories from multiple sources, a medical evaluation of general and neurological health, and a full cognitive assessment. In practice, the diagnosis is often made in individuals who meet only some of the criteria established by the DSM-V.

Treatment and management

The American Academy of Child and Adolescent Psychiatry (AACAP) established treatment as the support and education of family members, appropriate school placement, and pharmacology. Both pharmacological treatment and psychosocial treatment such as behavioral modification may be used.

Pharmacological treatment

Pharmacological treatment with psychostimulants is the most widely researched treatment for ADHD. This treatment has been used for childhood behavioral disorders since the 1930s. Psychostimulants are highly effective for approximately 75%–90% of children with ADHD. There are four psychostimulant treatments that have been demonstrated by hundreds of randomized controlled trials to consistently reduce the primary symptoms of ADHD: methylphenidate, dextroamphetamine, pemoline, and a mixture of amphetamine salts. These medications are only effective for one to four hours and so must be administered with the individual's school or work schedule. The medications are most effective for symptoms of hyperactivity, impulsivity, inattention, and the associated features of rebelliousness, aggression, and argumentativeness. They promote improved overall performance. Individuals who do not respond to one stimulant may respond to another. Those in whom psychostimulant treatment has been indicated require an assessment to determine which, if any, psychostimulant may improve their symptoms with the fewest side effects. According to guidelines established by the AACAP, stimulants are usually started at a low dose and adjusted weekly. According to the NIMH, the stimulants most commonly prescribed for ADHD include methylphenidate (Ritalin), dextroamphetamine (Dexedrine), and amphetamine (Adderall).

In December 1999, the National Institutes of Mental Health (NIMH) began the ongoing Multimodal Treatment Study of Children with ADHD (MTA), a landmark study that was one of the largest clinical studies ever conducted by the National Institutes of Health. The MTA

utilized 18 nationally recognized authorities in ADHD at six different university medical centers and hospitals to evaluate the leading psychosocial and pharmacological treatments for ADHD. The MTA indicated that long-term combination treatments and pharmacological treatment alone are both significantly superior to intensive behavioral treatments and routine community care in reducing most ADHD symptoms. Combined treatment was equal in efficacy to medication alone in modifying the core ADHD symptoms of inattention, hyperactivity, impulsivity, and aggression. Combined treatment was superior to medication alone in treating anxiety symptoms and in improving academic performance and social skills. Combined treatment also allowed children to be successfully treated with lower doses of medication. The NIH ADHD Consensus Conference of 1998 reported that several decades of research have established behavioral therapies to be very effective. However, the NIMH MTA study demonstrated that carefully monitored medication management is even more effective for the treatment of ADHD symptoms.

Some common side effects of psychostimulant therapy include insomnia, decreased appetite, stomachaches, headaches, and jitteriness. There may be rebound activation (a sudden increase in attention deficit and hyperactivity) after medication levels drop. Most side effects are mild; they tend to diminish over time and respond to changes in dosage. There is no evidence that height or weight is affected by psychostimulant treatment, but precautionary monitoring of growth for children taking stimulants is still recommended. Atomoxetine (Strattera) is the only nonstimulant medication approved for the treatment of ADHD. It has effects on the neurotransmitter norepinephrine, which may also play a role in ADHD. When Strattera has been prescribed to children with ADHD, more than 70% have shown significant improvement in their symptoms. A 2020 study conducted comparing methylphenidate and atomoxetine found comparable efficacy and compliance, and slightly higher satisfaction with methylphenidate.

Between 10% and 30% of individuals with ADHD do not respond to stimulant medication. For them and for those who cannot tolerate the side effects, there are other useful medications. The antidepressant bupropion has been shown to be effective for a lower percentage of patients than stimulant medication. Certain types of antidepressants are sometimes used to augment psychostimulant treatment.

Psychosocial treatment

Psychosocial treatments may be used alone or in conjunction with pharmacological treatment to manage ADHD symptoms. Behavioral treatment for children

KEY TERMS

Magnetic resonance imaging (MRI) scan—Noninvasive analysis of organs, large blood vessels, and soft tissues using magnetization without exposure to ionizing radiation.

White matter—The part of the brain that consists of fibers that establish long-distance connections between brain regions. It normally thickens as a child grows older, and the brain matures.

typically involves using time-out, point systems, and contingent attention (adults reinforcing appropriate behavior by paying attention to it).

Children with ADHD can present a challenge that places significant stress on the family. Skills training in psychosocial treatment for parents can help reduce this stress. Systematic programs conducted in specialized classrooms or summer camps by highly trained individuals may be highly effective for some children. Adults may need treatment designed to train them in coping skills for management of ADHD symptoms. These skills may include list-making systems or other such reminders to assist in the completion of important tasks. Psychosocial treatment of ADHD symptoms has been proven to be less effective than pharmacological treatment when used alone. Furthermore, psychosocial treatment must be consistently applied across multiple settings to be fully effective. Behavioral interventions focus on improving targeted behaviors or skills, but they are not as useful in reducing the core symptoms of inattention, hyperactivity, or impulsivity.

Educational accommodations for children with ADHD are federally mandated. Two federal laws that impact ADHD individuals are the Rehabilitation Act of 1973 and the Americans with Disabilities Act of 1990, which prohibit discrimination against individuals with disabilities in higher education and the workplace. Adults with ADHD are sometimes eligible for both protection and accommodation in higher education and the workplace under these laws. Organizations such as Children and Adults with Attention Deficit Disorder (CHADD) and the National Attention Deficit Disorder Association can provide information and support for individuals with ADHD.

Treatment controversies

Antidepressants known as selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, are not effective treatments for ADHD. Elimination diets, vitamin

QUESTIONS TO ASK YOUR DOCTOR

- My child has just been diagnosed with ADHD. How is that different, if at all, from the condition known as attention deficit disorder (ADD)?
- Can you tell me what causes my child's ADHD?
- Are there other medical conditions often associated with ADHD?
- What is the prognosis for my child's ADHD?

supplements, and dietary changes have also been proven to be ineffective. Rigorous controlled studies have failed to demonstrate that sugar exacerbates the symptoms of children with ADHD. Alternative therapies such as homeopathy, biofeedback, and hypnotherapy have not been shown to be effective. Similarly, there is no evidence to support the popularly held views that ADHD can be caused from excessive sugar intake, food additives, excessive television, poor parenting, or social and environmental factors such as poverty.

One highly controversial issue is whether there is over-diagnosis of ADHD and resultant over-prescription of stimulant medications. Special education legislation in the early 1990s increased general awareness of ADHD as a handicapping condition and provided the legal basis for accommodating ADHD-impaired students in the school setting. These legal mandates increased awareness of ADHD within the school system and may have inadvertently led to the inaccurate conclusion that ADHD is a new disorder or that it is overdiagnosed. Despite the increased awareness, the Executive Summary on Mental Health, a supplement to the Surgeon General's Report in 2001, indicated that 75% to 80% of youths with mental health illnesses do not receive the needed treatments. Any increased use of stimulants in the 1990s is thought to reflect better diagnosis and more effective treatment of this prevalent disorder, which is still underdiagnosed. Most underdiagnosis is thought to be due to inadequate information supplied to the healthcare provider.

Prognosis

When properly diagnosed and treated, ADHD can be well managed. Treatment often leads to increased satisfaction in life and significant improvement in daily functioning. Many people with ADHD lead highly successful and happy lives. With proper treatment, the prognosis for ADHD can be very good. However, medications do not cure ADHD; they only temporarily control

the symptoms. Although medications improve the prognosis and assist with symptom control, they cannot improve academic skills. The medications only help people to use those skills they already possess. Behavioral therapy and emotional counseling help individuals with ADHD to cope with their disorder.

Treatment may also mitigate risk factors for ADHD. A review of all long-term studies on stimulant medication and substance abuse, conducted by researchers at Massachusetts General Hospital and Harvard Medical School, determined that teenagers with ADHD who remain on medication have a lower probability of substance abuse than those who do not. Medications used properly at a young age may prevent additional later-onset emotional problems. People with ADHD who do not receive any form of treatment, either pharmacological or psychosocial, have a much poorer prognosis.

Atypical Singleton-Merten syndrome

Definition

Atypical Singleton-Merten syndrome is a newly discovered variant of a very rare multisystem genetic disorder characterized by calcifications (calcium deposits) in the major blood vessels near the heart, glaucoma, and

dental and skeletal abnormalities. The major difference between atypical Singleton-Merten syndrome (SGMRT2) and the typical form of the disorder (SGMRT1) in terms of clinical features is the absence of dental abnormalities in SGMRT2.

Both forms of the syndrome are named for the two American radiologists, Edward Singleton and David Merten, who first described the disorder in 1973. Other names for the typical form of the syndrome include Merten-Singleton syndrome, Singleton-Merten dysplasia, SM syndrome, and syndrome of widened medullary cavities of the metacarpals and phalanges, aortic calcification, and abnormal dentition. The name of the variant, “atypical Singleton-Merten syndrome,” was given by the discoverer of its causative gene in 2015.

Description

In order to understand why SGMRT2 is considered atypical, it is helpful to look first at the typical form of the disorder. SGMRT1 is characterized by abnormalities in several body systems: cardiovascular, musculoskeletal, ocular, and dental:

- **Cardiovascular:** Calcifications in the aorta, the mitral and aortic valves of the heart, and the pulmonary artery gradually narrow the diameter of these vessels and valves (stenosis), slowing the flow of oxygenated blood to body tissues. By late adolescence, a child with Singleton-Merten syndrome has high blood pressure, abnormal transmission of the electrical impulses that regulate the activity of cardiac muscle (a condition known as heart block), abnormal enlargement of the heart, and the risk of heart failure.
- **Musculoskeletal:** Musculoskeletal abnormalities begin to appear as early as four months of age. The infant’s muscles waste away (atrophy) and the remaining muscle tissue loses its tone (hypotonia). The child’s overall growth is often slowed, resulting in short stature, delayed motor development, and muscle contractures. Skeletal abnormalities include widening of the medullary cavities in the bones (phalanges) of the hands; scoliosis and kyphosis; displacement of the hips, high risk of tendon rupture, and a waddling gait as a result of muscular weakness; and osteoporosis by late adolescence.
- **Ocular:** Glaucoma develops in late childhood or early adolescence and may result in complete blindness.
- **Dental:** Abnormal mineralization of the jawbones leads to late eruption and early loss of both baby and permanent teeth. The permanent teeth may be malformed and have an unusually large number of cavities.

Some patients with SGMRT1 also develop a skin rash that resembles psoriasis, with thick, red, scaly patches that are most noticeable on the fingers.

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Autosome—One of the 22 chromosomes that are not involved in determining gender (chromosomes 1 through 22 and not the X or Y chromosome).

Calcification—The process by which tissue becomes hardened by the depositing of calcium in the tissue.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Gain-of-function mutation—A mutation that changes the gene's product such that it acquires a new and abnormal function.

Genetic heterogeneity—The occurrence of the same or similar disease, caused by different genes among different families.

Hyperkeratosis—Abnormal thickening of the outermost layer of the skin, the stratum corneum.

Interferon—Any of a group of cells signaling proteins that are made and released by cells in

response to the presence of viruses, bacteria, and other disease organisms. The name is derived from the way in which these proteins interfere with the replication of viruses by protecting cells from virus infections.

Kyphosis—Abnormal outward curvature of the spine resulting in a hunchback.

Medullary cavity—The marrow-filled cavity inside of a long bone (such as the femur).

Osteoporosis—Loss of bone density that can increase the risk of fractures.

Phenotype—An observable characteristic or trait of an organism as determined by its genetic makeup (genotype) and its interactions with the environment.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than 10 degrees to the right or left as the doctor faces the patient.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

Stenosis—The constricting or narrowing of an opening or passageway.

Genetic profile

The identification of SGMRT2 confirmed previous researchers' identification of the Singleton-Merten syndrome as marked by genetic heterogeneity, that is, that the same phenotype (an organism's visible features or traits) can result from different genetic mechanisms or from mutations in different genes. Although SGMRT1 was (and still is) considered to have an autosomal dominant inheritance pattern, a few cases of it appear to be sporadic (occurring at random for no apparent reason). SGMRT1 is associated with a mutation in the *IFIH1* gene (also known as the *MDA5* gene) on the long arm of chromosome 2 at 2q24.2. In early 2015, this *IFIH1* mutation was identified as a gain-of-function mutation, which means that the gene's product acquires a new and abnormal function. The *IFIH1* mutation triggers the production of an interferon that heightens the body's inflammatory response to a viral infection.

SGMRT2, in contrast, is associated with mutations in the *DDX58* gene located on the short arm of chromosome 9 at 9p21.1. This gene is involved in the recognition of viral proteins and plays a role in activating the immune system's response to the presence of a virus. Like SGMRT1, SGMRT2 is inherited in an autosomal dominant pattern.

Demographics

Both forms of Singleton-Merten syndrome are very rare; the prevalence is estimated at less than one person per million. As of 2015, only eleven cases of SGMRT1 from seven unrelated families had been reported worldwide. Males and females are equally affected, although in one of the families, all three patients were males.

SGMRT2 was identified in a Korean family in which eight members over four generations had the characteristic signs and symptoms of atypical Singleton-Merten syndrome. As with SGMRT1, males and females are equally affected. The pattern of inheritance is clearly autosomal dominant. It would be premature, however, to conclude from this initial case series of SGMRT2 that the disorder is more common among east Asians in general or Koreans in particular. Further research is required to determine whether the disorder is more common in some populations than in others.

Signs and symptoms

On the basis of the initial case series, the characteristic signs and symptoms of SGMRT2 are as follows:

- Cardiovascular: calcifications in the aorta, coronary arteries, and aortic valve; stenosis of the aortic valve
- Musculoskeletal: short stature, contractures in the joints of the hands, abnormalities in the bones of the hands and feet, deterioration of the end joints of the fingers, and calcifications in the tendons and ligaments
- Ocular: glaucoma and blindness in adolescence
- Dermatological: skin rash resembling psoriasis, abnormal thickening of the outermost layer of the skin (hyperkeratosis)
- Dental: no abnormalities of teeth or jaws

Diagnosis

The diagnosis of both forms of Singleton-Merten syndrome is based on observation of the symptoms that appear at various points in early childhood, later childhood, and adolescence. Infants and toddlers with the syndrome will usually show signs of muscle weakness, loss of muscle tissue, difficulties in walking, hip displacement, and other skeletal abnormalities. Those with *SGMRT1* will also show late eruption and/or premature loss of baby teeth, frequent dental cavities, and possible early loss of permanent teeth.

These signs, along with high blood pressure or abnormally frequent bone fractures in the patient's teenage years, warrant specialized tests to confirm or rule out Singleton-Merten syndrome. X-ray studies can be used to reveal the presence of calcium deposits in the valves and aorta of the heart. X-ray imaging can also be used to look for signs of osteoporosis and abnormalities in the medullary cavities in the bones of the hands and feet. Another test that can be performed is cardiac catheterization, which involves threading a long, thin, hollow tube called a catheter through the blood vessels leading to the heart. This procedure is done to evaluate the presence and extent of stenosis in these blood vessels and to determine the rate of blood flow through the chambers of the heart.

As of 2015, there were two laboratories in the United States that offered testing for mutations in the *IFIH1* gene as part of a panel for diagnosing Aicardi-Goutières syndrome, a rare genetic disorder characterized by inflammation of the brain and skin, with symptoms resembling those of systemic lupus erythematosus (SLE). There were, however, no laboratories offering genetic testing for mutations in the *DDX58* gene as of 2015.

Treatment and management

There is no cure for either form of Singleton-Merten syndrome. Treatment is directed at the specific symptoms in each individual. While children with atypical Singleton-Merten syndrome do not need the specialized

QUESTIONS TO ASK YOUR DOCTOR

- Do you think other families with the atypical form of Singleton-Merten syndrome will be identified? Is it possible that it might turn out to be the more common form of the disorder?
- Do you think there will soon be a molecular genetic test for *SGMRT2*?
- Do you think prenatal testing should be offered for this syndrome?

dental treatments required for those with *SGMRT1*, they do require medical and surgical care from several different types of specialists, including cardiologists, dermatologists, ophthalmologists, physical therapists, and orthopedic surgeons. Those with severe calcifications in the heart may require surgery to remove the calcium deposits, replace damaged valves, and prevent complete heart failure.

Children diagnosed with the syndrome should have regular eye examinations from early childhood to monitor for signs of glaucoma. Glaucoma surgery has been shown to be beneficial in preventing blindness in the patients.

Children with either form of Singleton-Merten syndrome will also need a range of special education programs and other social services. Their families should be offered genetic counseling.

Prognosis

The initial case series that led to the identification of atypical Singleton-Merten syndrome indicates that patients can live well into their reproductive years. The oldest person in the series was 56, and two other patients were in their mid-30s at the time of the study. It is possible that the cardiovascular abnormalities may shorten some patients' lifespans, but long-term follow-up of the affected family is necessary to clarify the prognosis of the disorder.

Autism spectrum disorders

Definition

Autism spectrum disorders (ASD) encompass a wide range of complex neurological and developmental disorders. ASD varies from mild to debilitating and is characterized by impairment in social functioning, communication, learning, reasoning, and behaviors. Signs and symptoms of ASD are evident from early childhood and often last throughout life.

Description

ASD is a variable neurological disorder that affects the structure and function of the brain and nervous system. It can interfere with communication, social interactions, understanding, and learning. It is a spectrum disorder because of the wide range in symptoms and severity. Although 15%–20% of people with ASD have severe intellectual impairment, 46% have average or above-average intellectual ability. For example, some children with ASD teach themselves to read before they are able or choose to talk. Some people with ASD have extraordinary talents in various areas, such as math, art, or music, and are termed “savants.”

People with ASD usually have problems interacting verbally and nonverbally and are often described as “being in their own world.” Those who develop speech often use pronouns—such as “I,” “me,” and “you”—incorrectly and may have difficulty understanding the purpose of speech. They may echo the comments of others (echolalia) or use phrases inappropriately. They often have problems recognizing social cues such as facial expressions and tone of voice. About one-third of children with ASD develop seizures in early childhood or adolescence.

Individuals with ASD may have hyperacute senses. They may be overly sensitive to bright lights, loud noises, or rough textures. Self-stimulating or repetitive behaviors—such as head banging, hand flapping, or rocking—may be attempts at self-calming when overstimulated. Other characteristic behaviors can include temper tantrums, fixations, or obsessions. Many people with ASD require strict routines and have difficulty adapting to any type of change.

Origins

The term “autism,” from the Greek word *autos* meaning “self,” was first used by the Swiss psychiatrist Eugen Bleuler for “isolated self,” indicating removal from social interaction. In the 1940s, the Austrian-American psychiatrist Leo Kanner used the term “early infantile autism” to describe children with a pattern of symptoms, but with some unique abilities, who did not appear to be emotionally disturbed or mentally retarded. At about the same time, the Austrian pediatrician Hans Asperger described children with a similar behavioral profile that became known as Asperger syndrome.

In 2013, the fifth edition of the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* significantly—and controversially—altered ASD classifications, defining it as a single spectrum disorder regardless of the symptoms or their severity. Previously, ASD was defined as a category consisting of four types:

- autistic disorder or “classic” autism
- Asperger syndrome, with well-developed language skills and milder symptoms primarily involving social behaviors
- childhood disintegrative disorder, in which children initially appear to develop normally, but lose language, movement, coordination, and other neurologic functions and develop autistic behaviors between the ages of three and ten years
- pervasive developmental disorder not otherwise specified (PDD-NOS) or “atypical” autism, with some symptoms of classic autism or Asperger syndrome.

Autistic teenager working with a speech therapist in a music workshop. (Amelie Benoist/Bsip SA/Alamy)

These terms are no longer used. Rather, patients are all described as having ASD.

Genetic profile

Studies strongly suggest the existence of a genetic predisposition to ASD, but the genetic profile is extremely complicated. If one identical twin has ASD, the risk that the other twin (who has inherited identical genes) is also affected may approach 90%. In contrast, the risk is much lower that a second non-identical twin is also affected. Likewise, in families with one child with ASD, the risk of having a second affected child is somewhere between 2% and 18%. Sometimes a parent or other relative of a child with ASD exhibits mild social or communicative impairment or repetitive behaviors. Some mental disorders, such as bipolar disorder, appear to occur more frequently in families affected by ASD. Nevertheless, most people with ASD have no family history of the disorder.

About 100 genes and 50 chromosomal abnormalities have been associated with ASD. However, another 500 to 1,000 genes appear to contribute to the risk of ASD. The potential involvement of so many different genes and

gene variants probably accounts for the range of symptoms seen in ASD. Most people with ASD have different combinations of gene variants or mutations (changes) in different genes. The largest study to date of genes that contribute to ASD, published in 2014, strongly implicated 33 different genes. Those conferring the most significant risk of ASD were genes involved in the formation of communications between brain cells, genes that controlled the expression of other genes, and genes that were regulated by environmental factors. The greatest risk factors for ASD were rare mutations in 107 different genes. The researchers identified gene mutations that increased the risk for ASD in boys by more than 20-fold. Another study published in 2014 reported that about 60% of the risk for ASD was due to both common and rare versions of genes inherited from the parents, with only about 2.6% of the risk attributable to spontaneous mutations that were not inherited from a parent. A study published in 2015 reported that, among siblings with ASD, only one-third had inherited similar gene variants from a parent, again indicating that genetic and environmental interactions are responsible. Furthermore, many people with some of the ASD-associated gene mutations have no symptoms of ASD. Some researchers have suggested

that every case of ASD is caused by a set of genetic and environmental factors unique to the individual.

ASD-associated genetic syndromes

Despite the large number of gene variations that appear to be associated with ASD—ranging from single point mutations in the DNA sequence of a gene to deletions or duplications of sections of DNA to large chromosome abnormalities—fewer than 20% of ASD cases have specific genetic causes. There are known genetic disorders that carry a risk for ASD and that can usually be detected with genetic testing. About 10% of children with ASD have Down syndrome, fragile X syndrome, tuberous sclerosis, or other known genetic disorders.

Fragile X syndrome—the most common cause of inherited intellectual disability—accounts for about 2% of ASD cases. Fragile X syndrome is caused by a defect in the *FMR1* gene located on the X chromosome. It almost exclusively affects males, since they have only one X chromosome inherited from their mother. Females have two X chromosomes, so they are unlikely to be affected even if they inherit one fragile X gene.

Tuberous sclerosis is caused by mutations in the *TSC1* and *TSC2* genes. It is a variable disorder characterized by under-pigmented skin patches, tumors, seizures, and mental retardation in some affected individuals. Up to 25% of patients with tuberous sclerosis have symptoms of ASD.

Phenylketonuria (PKU) is an inherited metabolic disorder in which the enzyme that breaks down the amino acid phenylalanine is defective or absent. Protein in the diet causes the buildup of phenylalanine in the body leading to mental retardation and autistic symptoms. In the United States, most newborns are tested for PKU and are treated with a phenylalanine-free diet, which prevents intellectual impairment and ASD.

Rett syndrome is a progressive neurological disorder that is caused by mutations in the *MECP2* gene and almost exclusively affects females. Girls with Rett syndrome develop normally until 18 months of age and then undergo a period of regression with loss of speech and motor skills. Girls with Rett syndrome have mental retardation and often exhibit autistic behaviors including constant hand wringing or hand washing.

Other risk factors

Researchers are attempting to identify other factors that interact with genetic susceptibility to cause ASD. These include other problems with connections in the brain, problems in the growth or overgrowth of brain regions, or metabolic or immune system problems that are

not caused by identified genetic factors. Among people with ASD, 89% are diagnosed with at least one other developmental disorder, such as learning disabilities or attention deficit disorder (ADD), and 10% are diagnosed with at least one psychiatric disorder. Other co-existing disorders may include Tourette syndrome or epilepsy. A small percentage of children born prematurely or with low birth weight are at higher risk for ASD. Children born to older parents are also at higher risk. Researchers have reported that pregnant women who took common antidepressants called selective serotonin reuptake inhibitors (SSRIs), especially during the first trimester, were at two–three times greater risk of having a child with ASD. Assisted reproductive technology (ART) has been reported to increase the risk of ASD, especially ART that injects sperm directly into the cytoplasm of the egg cell. The risk also appears to depend on the type of infertility being treated with ART. Other possible risk factors for ASD include infection or exposure to environmental chemicals, such as pesticides.

Demographics

It is difficult to determine the true incidence of ASD, particularly with recent changes in diagnostic criteria. However, ASD diagnoses have increased significantly in recent years. Some of this increase is due to improved awareness of ASD on the part of healthcare professionals and parents. In the past, children now diagnosed with ASD may have been diagnosed with developmental delay or mental retardation at one end of the spectrum or simply labeled as unusual or quirky at the other end of the spectrum. However, the increase in ASD cannot be explained by increased awareness or diagnoses alone. In the United States, ASD affects about one in 68 children, and recent North American, European, and Asian studies have reported an average incidence of 1%. A South Korean study reported a prevalence of 2.6%.

ASD occurs in all ethnic, racial, socioeconomic, and age groups. In the United States, it affects almost five times more males than females: one in 42 boys compared with one in 189 girls. However, some researchers believe that ASD is underdiagnosed in females because they are better than males at masking their symptoms, particularly symptoms involving social interactions.

Although the causes of ASD are unknown, there are clearly multiple factors contributing to symptoms that fall along the autism spectrum. These symptoms are believed to result from the interaction of multiple genes, termed multifactorial inheritance, and environmental factors that appear to occur during prenatal development. Studies have found irregularities in several brain regions in people with ASD, as well as abnormal levels of serotonin and other neurotransmitters. Such studies suggest a

KEY TERMS

Antipsychotics—Medications for reducing symptoms of a severe mental disorder such as schizophrenia; sometimes used for behavioral ASD symptoms.

Asperger syndrome—A term previously used to describe mild autism in individuals with normal intelligence and language skills; now classified as an ASD.

Assisted reproductive technology (ART)—Infertility treatments, including fertility drugs, artificial insemination, and in vitro fertilization.

Attention deficit disorder (ADD); attention deficit/hyperactivity disorder (ADHD)—Condition characterized by diverse symptoms including age-inappropriate attention span, hyperactivity, and impulsive behavior.

Catatonia—Psychomotor disturbances that can include stupor, rigidity, muteness, purposeless, or bizarre movements; may occur with a severe ASD.

Childhood disintegrative disorder—A type of ASD in which children develop normally until about age three or four and then, over a period of a few months, lose their previously learned motor, language, social, and other skills.

Down syndrome—A genetic disorder characterized by development delay, intellectual deficits, distinctive facial characteristics, and sometimes ASD.

Epilepsy—Recurrent seizures that temporarily affect awareness, movements, sensations or consciousness; sometimes associated with ASD.

Fragile X syndrome—A genetic disorder usually affecting males, caused by a defective gene on the X chromosome, and associated with mental retardation and often ASD.

Neurotransmitter—Any of a variety of molecules that facilitate nerve impulses throughout the nervous system with the purpose of influencing and balancing thought, movement, and other body functions.

Off-label—The decision to prescribe a drug for purposes other than those specifically approved by the U.S. Food and Drug Administration.

Pervasive developmental disorder not otherwise specified (PDD-NOS)—A term previously used to describe individuals who met some but not all of the criteria for classic autism or Asperger syndrome; now classified as an ASD.

Phenylketonuria (PKU)—A genetic disorder of amino acid (phenylalanine) metabolism that, if left untreated, causes mental retardation and possibly ASD.

Rett syndrome—An inherited progressive neurodevelopmental disorder that affects females, usually beginning in infancy, and characterized by slow brain growth, cognitive and motor deterioration, and possibly ASD.

Savants—People with ASD who have unusual abilities in areas such as art, math, or music.

Tuberous sclerosis—A genetic disorder of the skin and nervous system involving the formation of small tumors in various organs and sometimes causing ASD.

possible disruption in early prenatal brain development. Increased head size or rapid head growth can be an early sign of ASD. Brain-imaging studies have suggested that abnormal brain development during the first few months of infancy may play a role. This suggests that defects in growth factors may be involved. It has been conclusively demonstrated that ASD is not caused by either parental behaviors or childhood vaccines.

Signs and symptoms

Just as the causes of ASD appear to be unique to each individual, so are the signs and symptoms. Although differences in brain growth may be evident by six months-of-age, and ASD symptoms are always present by at least 12–18 months-of-age, signs are frequently not recognized until children fail to begin speaking. Furthermore, some children with ASD appear to develop

normally and then regress, usually between the ages of one and two years—they stop using language or previously acquired social or play skills.

Impaired social interaction is a hallmark of ASD. Infants may not respond to being held or may focus intently on one item to the exclusion of everything else. Children with ASD may:

- fail to respond to their name
- avoid eye contact
- be unresponsive to social cues such as facial expressions or tone of voice
- fail to attach to parents or caregivers
- demonstrate a lack of empathy
- have little or no interest in human contact or making friends

- display inappropriate laughing or giggling
- fail to engage in imaginative or pretend play
- avoid group play
- engage in repetitive movements
- engage in self-abuse such as biting or head banging

Communication signs of ASD may include:

- language delay or absence, such as no babbling or pointing by 12 months and no single words by 16 months or two-word phrases by two years
- impaired speech
- meaningless repetition of words or phrases
- use of gestures instead of words
- concrete or literal interpretations of words or phrases
- inability to initiate or conduct conversations
- referring to oneself by name rather than a personal pronoun
- speaking in a sing-song voice

Other signs of ASD can include:

- rigid or flaccid muscles when being held
- repetitive motions such as hand flapping
- temper tantrums or screaming fits
- resistance to change
- hyperactivity
- fixations or obsessive interest in an activity, idea, or person
- overreaction to sensory stimuli such as noise, lights, or textures

Diagnosis

Early diagnosis of ASD and early intervention greatly improve outcomes. However, children with ASD often go undiagnosed until after age three, when they are examined because of speech delays and may undergo assessment for hearing impairment. It can be particularly difficult to recognize ASD in children who are only mildly affected or who have other serious conditions that mask ASD symptoms. Initial screening is often based on parental questionnaires or a combination of parent and physician observations. Children showing signs of ASD should undergo comprehensive evaluations that include neurologic assessment and cognitive and language testing by a team of specialists, usually over a period of time. The team may include a psychologist, neurologist, psychiatrist, speech therapist, and other specialists. Other diagnostic work may include chromosome analysis and DNA testing for specific genetic disorders, brain-imaging scans for any structural anomalies, and electroencephalography (EEG) for brain electrical activity and evidence of epilepsy.

The *DSM-5* standardized criteria for ASD diagnosis include:

- persistent deficits or impairments in social communication and interaction, including “social-emotional reciprocity” such as initiating and responding to interactions, conversations, and sharing of interests or emotions; nonverbal communicative behaviors; and developing, maintaining, and understanding relationships
- “restricted, repetitive patterns of behavior,” including stereotyped or repetitive movements, object use, or speech; inflexible insistence on routines, sameness, or ritualized patterns of behavior; abnormal highly restrictive or fixated interests; and over- or under-reactions to sensory input
- symptoms that are present during early development, even if these are not obvious until later on or are masked by learned strategies
- symptoms that cause significant social or occupational impairment or other serious impairment of functioning
- symptoms that are not better explained by intellectual disability or global development delay, although these may co-exist with ASD

Individuals who were previously diagnosed under *DSM-4* criteria with autistic disorder, Asperger syndrome, or PDD-NOS are now diagnosed with ASD. Patients with deficits only in social (pragmatic) communication disorder. Under *DSM-5*, ASD is further specified as:

- with or without intellectual impairment
- with or without language impairment
- with or without an associated medical or genetic condition or known environmental factor
- with or without an associated neurodevelopmental, mental, or behavioral disorder
- with or without associated catatonia

Treatment and management

Language and behavioral therapies form the cornerstones of ASD treatment and management, although interventions depend on the individual’s specific problems and their severity and any unique abilities. Intensive interventions beginning as early as possible have the best outcomes. Healthcare professionals, therapists, educators, and families must work as a team for the effective treatment and management of ASD.

Interventions include:

- highly structured, specialized education programs tailored to individual needs
- speech, language, and communication therapy

QUESTIONS TO ASK YOUR DOCTOR

- How is ASD diagnosed?
- How severe is my child's ASD?
- Are there genetic tests for ASD?
- What treatments and interventions do you recommend for my child?
- What is my child's prognosis?

- occupational therapy and skills training for developing fine motor skills and basic self-help and functional skills such as grooming
- intensive, highly structured skills training, such as applied behavior analysis for social and language skills
- behavior modification using positive reinforcement
- various other behavioral therapies
- auditory and other sensory integration training
- vision therapy
- physical therapy
- music therapy
- dietary interventions, which can be helpful for some children
- family counseling for parents and siblings

Drugs

As of 2015, the only drugs specifically approved by the U.S. Food and Drug Administration (FDA) for treatment of ASD in children aged 5 to 16 are the antipsychotics risperidone and aripiprazole for reducing symptoms such as temper tantrums, aggression, or self-harm. However, many medications are prescribed off-label (not specifically approved by the FDA for ASD or for children of a certain age) for reducing problems at home and school:

- antipsychotics for reducing repetitive behaviors, hyperactivity, and attention problems, as well as aggression and other serious behaviors
- antidepressants, such as fluoxetine or sertraline, for depression, anxiety, reducing repetitive behaviors, and possibly controlling aggression, although it is unclear whether these drugs are effective
- stimulants such as methylphenidate (Ritalin) for hyperactivity, although children with ASD are less likely to respond to methylphenidate than those with attention deficit/hyperactivity disorder (ADHD) and also have more side effects from the drug
- anticonvulsants for seizures

- other medications for anxiety, depression, ADHD, or obsessive-compulsive disorder

Clinical trials

As of 2015, there were more than 200 open clinical trials for ASD. Current listings are available at <https://clinicaltrials.gov/search/open/condition=%22Autistic+Disorder%22> Examples of clinical trials include:

- computer-based training for appropriately creating and responding to facial expressions
- social interventions for classroom use
- parental interventions for reducing and preventing ASD-related disability in high-risk children
- a new medication for improving functioning in children with fragile X syndrome

Prognosis

Although there is no cure for ASD, behaviors can and do moderate over time. ASD symptoms in many children improve with age and treatment, although some children with ASD develop depression or behavioral problems during adolescence. Prognosis ultimately depends on the individual's intellectual and communicative abilities and the severity of behavioral problems. Children whose language skills regress before the age of three appear to be at higher risk for epilepsy or other seizure-like brain activity. Nevertheless, interventions have improved considerably in recent years and—especially with early, intensive intervention—many children with ASD can become independent, highly functioning adults. Nevertheless, many adults with ASD require lifelong services and supports.

Autologous germline mitochondrial transfer

Definition

Autologous germline mitochondrial transfer (AUGMENT) is an experimental procedure used to enhance fertility. It involves transferring mitochondria from a woman's own egg cells into eggs used for in vitro fertilization (IVF). Mitochondria are structures found in the cells that produce most of the energy needed to power the cells. This procedure can make it easier for women with infertility problems to have children, especially older women who have fewer mitochondria in their eggs.

Description

What is AUGMENT?

As women age, the DNA (genetic material) in their mitochondria (mtDNA) has acquired more mutations,

KEY TERMS

Cells—Building blocks that provide structure to the body and perform all of the functions of the body. Cells contain genetic information and can copy themselves. There are many different types of cells in the body.

In vitro fertilization (IVF)—A procedure that involves creating embryos in the lab by mixing eggs and sperm and transferring the embryos to the uterus.

Mitochondria—Structures found in the cell (organelles) surrounded by two layers of membrane. Mitochondria turn energy from food into energy that powers the cell. They also help the cell produce heat and store calcium, and they help choose which damaged cells need to be destroyed.

Mitochondrial DNA (mtDNA)—The DNA (genetic material) found in the mitochondria. MtDNA contains the instructions for about 37 genes. These genes produce proteins that help the mitochondria function. MtDNA is only passed from the mother to her offspring.

Mitochondrial Mutation—Variation in the mitochondrial DNA that can affect how well the mitochondria functions.

Stem cells—Cells that can transform into any different type of cell and can make copies of themselves indefinitely.

Oogonial stem cells—Cells that develop into mature eggs.

which can interfere with the normal functioning of the mitochondria and reduce the number of them in a cell. Mutations in the mtDNA of an egg can interfere with fertilization. Normally, mitochondria in the egg increase from 6,000 in the immature egg to 300,000 to 400,000 or more in the mature egg. The number of mitochondria increases because of the increased need for energy during fertilization and embryo development.

Older women who are experiencing infertility typically have a decreased number of mitochondria in their eggs, and the fewer mitochondria present do not function as well. The result can be problems with embryo development and infertility. The idea behind AUGMENT is that increasing the number of mitochondria in an egg could improve fertilization and embryo development.

QUESTIONS TO ASK YOUR DOCTOR

- Could AUGMENT help me overcome my fertility problems.?
- What are the limitations of the treatment?
- Is this treatment available in your clinic?

How AUGMENT is Done

The AUGMENT procedure uses oogonial stem cells from the ovaries. Oogonial stem cells are egg precursor cells that can develop into eggs. These stem cells possess the same mitochondria as egg cells. The advantages of these stem cells are that their mtDNA has fewer mutations, and the mitochondria appear to function better than in regular eggs, likely because the stem cells are dormant cells and have a lower rate of age-related DNA damage.

During AUGMENT, a piece of the ovary is removed and grown in a test tube that contains ovarian tissue. The stem cells are then identified and isolated, and mitochondria are removed from these cells. The isolated mitochondria and sperm are injected into an egg. Like in conventional IVF, embryos that develop from this procedure are implanted in the uterus. Two limitations of AUGMENT are that it can be a challenge to find ovarian tissue to grow the stem cells, and it is difficult to evaluate the quality of eggs produced.

Mitochondrial Replacement Using Donors

Mitochondrial replacement therapy can also be done using mitochondria from other women (donors). This procedure is sometimes called ‘three-person IVF.’ In addition to improving fertility, mitochondrial replacement therapy from donors with normal mtDNA can help prevent disease. In this case, mitochondria from donors with normal mtDNA can be used for women who have mutations in their mtDNA that could cause disease in their offspring. Mitochondrial replacement therapy could prevent mitochondrial abnormalities in children. Using donors for mitochondrial transfer is banned in the U.S., because it is considered a modification that could affect future generations and have unintended consequences. AUGMENT, which is legal in the U.S., solves the potential problem of having “foreign” mitochondria present in the resulting embryos. It can also decrease the expense and difficulty of finding donor mitochondria. However, it cannot be used to prevent mitochondrial disorders in children.

AUGMENT Clinical Trials

At least three fertility centers have had successful clinical trials using AUGMENT on women who have previously had poor outcomes using IVF. Ninety-three patients recruited from The Toronto Centre for Assisted Reproductive Technologies (TCART) (Toronto, Canada) and FAKIH IVF (Dubai, United Arab Emirates) were treated with AUGMENT through the OvaScience Global Registry program. At TCART, the pregnancy rates before treatment with AUGMENT were around 1.3% and after treatment they were 35%. At FAKIH IVF, the pregnancy rates before treatment with AUGMENT were around 2% and after treatment they were around 22%. Eleven other patients from GenArt Women’s Health and Reproductive Biotechnology Centre in Turkey were also treated with AUGMENT with a pregnancy rate that increased to around 40%.

Measuring Mitochondrial DNA for Embryo Selection

Interestingly, although poorer-quality eggs tend to have lower amounts of mtDNA, poorer-quality early embryos tend to have higher amounts of mtDNA. Some researchers have found that embryos will not implant in the uterus if their levels of mtDNA are too high. However, not all research supports this claim, and further research is necessary before it is used by fertility centers to help select embryos.

Autosomal dominant multiple pterygium syndrome

Definition

Autosomal dominant multiple pterygium syndrome refers to a rare genetic disorder that belongs to a group of congenital musculoskeletal disorders characterized by abnormal webs of skin or soft tissue called pterygia on the neck and other body locations, in addition to other abnormalities. This group of disorders is called multiple pterygium syndrome, or MPS, and is marked by genetic heterogeneity. Most known forms of MPS are inherited in an autosomal recessive pattern; autosomal dominant MPS is distinguished by the gene associated with it as well as by its autosomal dominant pattern of inheritance.

Description

MPS in general is a syndrome in which infants are born with webs of skin called pterygia around the base of the neck, between the fingers, inside the elbows, and behind the knees. These webs may become large enough to restrict the movement of the fingers and limbs. In addition to pterygia, children with MPS also have arthrogryposis (joint contractures in two or more regions of the body), camptodactyly (permanent bending of the middle joint of one or more fingers), short stature, a small rib cage, abnormal curvature of the spine (scoliosis), humpback (kyphosis), fusion of some of the vertebrae in the spine, and unusual or malformed facial features.

The contractures and pterygia in MPS are thought to be the result of fetal akinesia, a condition in which the fetus's movements in the mother's uterus slow down as the result of structural abnormalities of the uterus, genetic mutations in the fetus, or an inadequate amount of amniotic fluid. The musculoskeletal abnormalities found in MPS are nonprogressive, which means that they do not become worse over time.

Genetic profile

The two most common forms of MPS have an autosomal recessive inheritance pattern, which means that both parents must have a genetic mutation in order for the offspring to develop MPS. One form is called MPS, lethal type because the affected fetus dies before or shortly after birth. Lethal-type MPS is caused by mutations in any of three genes, all on the long arm of chromosome 2: the *CHRNA1* gene at 2q31.1, the *CHRNA2* gene at 2q37.1, and the *CHRNA3* gene, also at 2q37.1.

The nonlethal type of autosomal recessive MPS is also known as Escobar syndrome. It is also caused by mutations in the *CHRNA3* gene. Children with Escobar syndrome have the pterygia, arthrogryposis, fusion of spinal vertebrae, short stature, and facial deformities associated with MPS. Their knee joints may lack kneecaps. Boys may have an unusually small penis and undescended testicles (cryptorchidism), and females may lack the labia majora (external genital folds). The facial deformities of Escobar syndrome include epicanthal folds around the eyes, drooping eyelids (ptosis), an abnormally small jaw (micrognathia), low-set ears, abnormally widely set eyes (hypertelorism), cleft palate, an unusually small mouth, an abnormally long philtrum, and a flat, expressionless face. This form of MPS is named for the clinician who first reported it in 1978.

There have been occasional reports of autosomal dominant forms of MPS in the medical literature from 1980 onward. In 1988, a pair of British researchers reported on a family with four members affected by an autosomal dominant form of MPS, although they did not identify a specific gene associated with the syndrome. In 1996 a group of researchers in Utah suggested renaming this autosomal dominant form of MPS distal arthrogryposis type 8 or DA8. They also did not link the syndrome to a specific gene.

In May 2015, an international team of researchers reported that they had traced autosomal dominant MPS to a mutation in the *MYH3* gene on the short arm of chromosome 17 at 17p13.1. This gene codes for a muscle protein called embryonic skeletal muscle myosin heavy chain 3. Myosin plays a role in cell movement, as well as the composition of muscle fibers. The form of myosin encoded by the *MYH3* gene is active during fetal development and is critical to normal muscle development in the fetus.

Mutations in the *MYH3* gene are associated with two other congenital arthrogryposis syndromes, Freeman-Sheldon syndrome and Sheldon-Hall syndrome. Both of these syndromes are associated with multiple congenital contractures. A major difference between the mutations

KEY TERMS

Arthrogryposis—A congenital musculoskeletal condition in which the infant has contractures of the joints in two or more areas of the body.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Camptodactyly—Abnormal bending of the middle joint of the finger. It is most often found in the little finger but may affect any finger.

Congenital—Refers to a disorder that is present at birth.

Contracture—An abnormal and usually permanent shortening and contraction of a muscle or tendon that causes a deformity or subnormal range of movement.

Epicanthal fold—A wrinkle in the skin extending from the nose up to the eyebrow; it is sometimes associated with genetic anomalies.

Fetal akinesia—A condition in which lack of fetal movement (akinesia) during pregnancy results in musculoskeletal abnormalities, underdevelopment of the lungs, and/or misshapen facial features. Fetal akinesia can result from a variety of conditions, ranging from abnormalities in the structure of the mother's uterus to infections or genetic disorders that affect fetal development.

Genetic heterogeneity—The production of apparently identical genetic disorders by different genetic mechanisms or by different genes at different positions on the chromosomes.

Kyphosis—Abnormal outward curvature of the spine resulting in a hunchback.

Micrognathia—The medical term for an undersized or underdeveloped jaw.

Philtrum—The center part of the face between the nose and lips that is usually depressed.

Ptosis—Drooping of the upper eyelid.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than ten degrees to the right or left as the doctor faces the patient.

in the *MYH3* gene that underlie these two disorders and those associated with the autosomal dominant form of MPS, however, is that the mutations occur in different portions of the gene. All myosin genes have three

domains known as the head, neck, and tail; each domain has different functions. The tail domain, which is the most important for the present discussion, determines the role of a particular myosin. The mutations linked to the Freeman-Sheldon and Sheldon-Hall syndromes are found in the head and neck of the *MYH3* gene, whereas the mutations linked to MPS were found in the tail. This finding means that the autosomal dominant form of MPS results from a different developmental mechanism than the congenital arthrogryposis syndromes. The researchers also suggest that the location of the *MYH3* mutation in the tail of the gene indicates that embryonic myosin is important in fetal skeletal as well as muscle development.

Demographics

All forms of MPS are very rare; fewer than 70 cases have been reported in the medical literature since the 1970s. Many cases of autosomal recessive MPS were found in consanguineous families, meaning that the parents of the affected children were closely related by blood as well as marriage.

The demographics of the autosomal dominant form of MPS are difficult to establish at present because the disorder was reported only in 2015, and the findings are based on only four families. More case studies will be required to obtain a clearer understanding of the demographics of the disorder.

Signs and symptoms

According to the authors of the 2015 article, the major signs and symptoms of autosomal dominant multiple pterygium syndrome are musculoskeletal: the characteristic pterygia, camptodactyly of the hands, scoliosis, and fusion of some of the spinal vertebrae. Facial deformities or abnormalities were not mentioned.

Diagnosis

Diagnosis of MPS and the congenital arthrogryposis syndromes can be made before birth by fetal ultrasound. The ultrasound images will reveal such features as scoliosis of the spine, clenched fingers, bent legs, and other evidence of contractures. Ultrasound imaging can also detect fetal akinesia.

Molecular genetic testing is available for the genes associated with the lethal form of MPS and with Escobar syndrome. Genetic testing is also available for mutations in the *MYH3* gene at a number of different laboratories in the United States and Europe.

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever seen or treated a patient with any form of MPS?
- Do you think more cases of the autosomal dominant form of MPS will be identified?
- What treatments would you recommend for a child with MPS?
- Would you recommend genetic testing for other family members when a child is diagnosed with MPS?

Treatment and management

Treatment of the contractures, skeletal abnormalities, and pterygia associated with MPS usually involves a team of specialists, including a pediatrician, orthopedic surgeon, and plastic surgeon. Correction of the spinal abnormalities should be undertaken before five years of age to prevent permanent scoliosis. Children with unusually small rib cages should be monitored carefully for pneumonia and other respiratory disorders, as they are at increased risk of these infections.

Correction or removal of pterygia is usually performed by a plastic surgeon. Great care must be taken when removing the excess soft tissue to ensure that any blood vessels or nerves in the webbing are not damaged. Plastic surgery may also be performed to repair cleft palate or other facial deformities associated with the Escobar type of autosomal recessive MPS.

As children with MPS grow older, they should receive appropriate physical therapy for their musculoskeletal problems. They may also need counseling to help them cope with social difficulties resulting from their physical limitations or facial features. Intellectual disability, however, is not usually associated with MPS, and children with either the autosomal recessive or autosomal dominant form should be able to complete their schooling.

Prognosis

The Escobar type of MPS and the autosomal dominant form of the disorder are not life-threatening. Most patients are thought to have normal life expectancy. Follow-up studies of the known cases of the autosomal dominant form of MPS will be needed, however, to provide a more specific prognosis.

AUTS2 syndrome

Definition

AUTS2 syndrome is a genetic disorder presently classified as an autism spectrum disorder or ASD. Children diagnosed with these disorders are characterized by abnormal behaviors and difficulties interacting socially

with others, problems with spoken as well as nonverbal communication, and stereotypy (repetitive gestures, behaviors, or utterances). In fact, one alternate name for AUTS2 syndrome is autism spectrum disorder with AUTS2 deficiency. The *AUTS2* gene was identified as the cause of the syndrome in 2013. Another alternate name for AUTS2 syndrome is mental retardation, autosomal dominant 26.

Description

Patients diagnosed with AUTS2 syndrome have many of the same characteristics as patients with other ASDs; however, they have more severe developmental delays, intellectual disability and other learning disabilities, feeding difficulties, and deformities of the face and skeleton less often found in other ASDs. These additional characteristics help to explain not only why one of the alternate names for the disorder is mental retardation, autosomal dominant 26, but also why an alternate name for the *AUTS2* gene itself is *MRD26*.

In addition to AUTS2 syndrome, mutations in the *AUTS2* gene have been associated with such other neurological disorders as dyslexia, epilepsy, visual impairments, bipolar disorder, and alcohol addiction. As of 2015, however, the mechanisms and genetic pathways of the gene were not well understood. It is possible that further research will clarify not only the role of the *AUTS2* gene in human neurological development, but also the relationship of AUTS2 syndrome to other ASDs and other single-gene disorders.

Genetic profile

The *AUTS2* gene was first identified in 2002 when researchers were examining a pair of identical twins diagnosed with ASD. The gene had been disrupted by a balanced translocation, which is a chromosomal abnormality caused by an exchange of material between two nonhomologous chromosomes. In a balanced translocation, the genetic material is evenly exchanged between the two chromosomes, with no extra or missing genetic material. The *AUTS2* gene was mapped to the long arm of chromosome 7 at 7q11.22. The gene is sometimes referred to as the *KIAA0442* or *MRD26* gene, but *AUTS2* has become the most common identifier. It stands for “autism susceptibility candidate 2.” The gene codes for a protein that is strongly expressed in the human central nervous system, which would account for its association with neurodevelopmental disorders; however, there is much that is still unknown about the function of the *AUTS2* gene.

The gene is inherited in an autosomal dominant pattern, which means that only one copy of the

KEY TERMS

Autism spectrum disorder (ASD)—A general term for a group of neurodevelopmental disorders characterized by difficulties in social interactions, significant abnormalities in speech patterns, and limited but repetitive interests and activities. AUTS2 syndrome is classified as an autism spectrum disorder.

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Autosome—One of the 22 chromosomes that are not involved in determining gender (chromosomes 1 through 22 and not the X or Y chromosome).

Dysmorphic—Referring to a malformed or misshapen body part.

Hypotonia—Low or poor muscle tone, resulting in floppy limbs.

Kyphosis—Abnormal outward curvature of the spine resulting in a hunchback.

Microcephaly—Abnormal smallness of the head; it often is associated with intellectual disability.

Nonhomologous—Referring to chromosomes that are not members of the same pair.

Ptosis—Drooping of the upper eyelid.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than 10 degrees to the right or left as the doctor faces the patient.

Stereotypy—A repetitive movement, gesture, or utterance; examples include head banging, rocking, or repeatedly crossing and uncrossing the legs. Stereotypy is found in persons with intellectual disabilities and some forms of schizophrenia, as well as autism spectrum disorders.

Translocation—A chromosomal abnormality that occurs when two nonhomologous chromosomes exchange genetic material. A translocation is said to be balanced if the genetic material is evenly exchanged, with no missing or extra genes. In an unbalanced translocation, the genetic material is not evenly exchanged, and there may be extra or missing genes.

mutation is required for the disorder to appear. As of 2015, it was thought that AUTS2 syndrome is a single-gene disorder, which distinguishes it from other ASDs.

Demographics

The prevalence of AUTS2 syndrome is unknown, largely because the disorder was first described in the medical literature only in 2013. The first report consisted of a case series of 17 patients, all Europeans. Later reports were of single patients identified in China and the United States, respectively, and two additional patients in Belgium and the Netherlands. The frequency of the disorder is estimated to be less than one person per million.

AUTS2 syndrome has been diagnosed in patients of various ages, ranging from 11 months to 32 years of age at the time they were examined. It is not yet known, however, whether the syndrome is more common in some racial or ethnic groups than in others.

Signs and symptoms

The major characteristics of AUTS2 syndrome, which vary somewhat in severity from patient to patient, are as follows:

- autistic behaviors, including difficulties in social interactions and delayed speech
- significant intellectual and learning disabilities
- low birth weight and feeding difficulties
- microcephaly (unusually small head) and unusually short stature
- dysmorphic facial features: unusually widely spaced eyes (hypertelorism), drooping eyelids (ptosis), a prominent tip on the nose, and a narrow mouth
- cerebral palsy
- skeletal abnormalities: scoliosis and kyphosis

Some patients diagnosed with AUTS2 syndrome have the following additional symptoms:

- attention deficit hyperactivity disorder
- hypotonia (poor muscle tone)
- structural abnormalities in the brain

Diagnosis

ASDs in general are diagnosed in late infancy or early childhood on the basis of such symptoms as absence of recognition of parents and other familiar persons, abnormal reactions to sounds or objects in the environment, stereotyped behaviors, delayed speech or abnormal use of language, and resistance to change. There are several checklists that can be administered to the child's parents or used by the pediatrician to screen young children for signs of an ASD. The Centers for Disease Control and Prevention (CDC) recommends that screening should be done twice, when the child is

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever seen or treated a patient with any form of MPS?
- Do you think more cases of the autosomal dominant form of MPS will be identified?
- What treatments would you recommend for a child with MPS?
- Would you recommend genetic testing for other family members when a child is diagnosed with MPS?

18 months old and again at 24 months of age. There are two reasons for early screening: to begin treatment as early as possible if the child has a high score on the checklist and to evaluate other children in the family for possible ASDs, since the disorders are known to be at least partly heritable.

Children who are thought to show signs of an ASD on the basis of the checklist are then given a follow-up comprehensive evaluation by a team of several different specialists (typically a neurologist, a psychiatrist, a speech therapist, and a child psychologist). As of 2015, there was no evidence that MRIs or other neuroimaging studies are useful in diagnosing ASDs, although electroencephalography is sometimes used to rule out seizure disorder. In addition, the child's hearing is usually tested to make sure that delayed speech is not the result of a hearing impairment.

In the specific case of AUTS2 syndrome, the diagnosis can be confirmed by genetic testing, as the syndrome is presently considered a single-gene disorder.

Treatment and management

There is no cure for AUTS2 syndrome or for any other ASD. Treatment is highly individualized and tailored to the patient's specific symptoms and their severity. Patients with AUTS2 syndrome are presently treated with a combination of special education, speech therapy, and antiseizure medications for those with epilepsy. It is possible that follow-up studies of the patients who have been identified since 2013 will lead to more detailed treatment recommendations.

Prognosis

The prognosis for patients with AUTS2 syndrome depends on the severity of their intellectual disability. Those less severely affected may be able to complete

some schooling and live by themselves, but most will require home or residential care throughout their lives. At present, AUTS2 syndrome is not thought to affect patients' life expectancy; however, since the *AUTS2* gene has been linked to acute lymphoblastic leukemia and certain other cancers as well as AUTS2 syndrome, it is possible that patients diagnosed with the syndrome are at increased risk of cancer. More research is required to investigate this question.

B

Bardet-Biedl syndrome

Definition

Bardet-Biedl syndrome (BBS) is a condition that primarily affects vision, kidney function, limb development, growth, and intelligence.

Description

BBS is a genetic condition that most often involves visual loss, obesity, polydactyly, learning delays, problems with the genitourinary system, and kidney problems, although there may be other clinical features as well. BBS expresses itself differently from person to person, even among members of the same family.

Genetic profile

BBS is a genetically heterogeneous condition; this means that it has more than one known genetic cause. There are fourteen genes known to be associated with the condition and another four that are likely associated. The gene *BBS1* is located on chromosome 11 and is found in 23% of those that have a clinical diagnosis of BBS. *BBS10* is located on chromosome 12 and is found in 20%. The other genes are found in 8% or fewer cases. The 18 associated mutations are found in 70%–80% of people with BBS. Therefore, it is likely that additional genes that have not yet been identified account for the remaining cases. Research suggests that the *BBS1* gene may be associated with milder visual loss, and those with *BBS10* may have more difficulty with diabetes and obesity. Research suggests that various types of cilia are affected by the *BBS* genes and result in the clinical features. For example, defects in the movement of proteins important in the retina lead to cell death and cause retinitis pigmentosa. Regardless of the gene involved, BBS displays an autosomal recessive inheritance pattern. This means that the condition occurs when an individual inherits two mutated copies of a *BBS* gene. If one copy is normal, the individual does not have BBS. This individual is

called a carrier of BBS and can pass the gene on to the next generation.

Research indicates that people who inherit one abnormal *BBS* gene and one normal gene may be at risk for some of the health problems seen in BBS. Compared to the general population, these *BBS* gene carriers are more likely to develop high blood pressure, diabetes mellitus, and kidney disease, including kidney cancer. Some research indicates that about 5% of cases of BBS may be caused by the combination of three genes rather than just two, but little is known about this type of inheritance for BBS yet.

Demographics

BBS affects people around the world. However, it is most common in the Middle East, especially in the Arab and inbred Bedouin populations of Kuwait. In these groups, it may affect as many as 1 in 13,500 individuals. The incidence is almost as high in Newfoundland, where as many as 1 in 17,500 individuals has BBS. Outside of these areas, researchers estimate that BBS affects only 1 in 100,000 to 160,000 people.

The specific genetic cause of BBS differs by family and geographic location. For example, in the Middle East, BBS appears to be associated with *BBS1*, 3, and 4 located on chromosomes 11, 3, and 15 respectively. However, in patients of European descent, BBS appears to be associated with *BBS1* and 10 located on chromosomes 1 and 12.

Signs and symptoms

Due to the subtlety of outward clinical features in some cases, medical care providers may not immediately suspect BBS. It becomes a consideration in children with polydactyly, although this condition has many other causes. BBS is also suspected when additional abnormalities emerge as the child develops. In boys, genital abnormalities become evident soon after birth. In almost all patients, obesity and retinal degeneration begin in early

KEY TERMS

Brachydactyly—Abnormal shortness of the fingers and toes.

Cilium (plural, cilia)—A slender protuberance projecting from the body of a cell involved either in sensory functions or motility in the cell.

Electroretinogram (ERG)—A measurement of electrical activity of the retina.

Intravenous pyelogram—An x-ray assessment of kidney function.

Polydactyly—The presence of extra fingers or toes.

Retinitis pigmentosa—Degeneration of the retina marked by progressive narrowing of the field of vision.

Syndactyly—Webbing or fusion between the fingers or toes.

childhood. Learning disabilities, if present, are identified in school-aged children if not earlier. Failure to menstruate leads to diagnosis of some adolescent girls. Infertility brings some young adults to medical attention. Kidney disease is progressive and may not become obvious until adulthood.

Due to progressive degeneration of the rods and cones in the retina, vision damage occurs in all patients. Specific vision defects include poor night vision during childhood, severe myopia (nearsightedness), glaucoma, and cataracts. Ninety percent of patients suffer from retinitis pigmentosa, a condition in which the field of vision progressively narrows. This finding often leads to the diagnosis. Seventy-five percent of individuals with BBS will become legally blind. The average age of legal blindness is age 15–20 years.

Fifty-three to eighty-two percent of infants with BBS are born with a kidney defect affecting kidney structure, function, or both. The specific abnormality varies from patient to patient and may be aggravated by lifelong obesity. Obesity most often occurs in the truncal area and is found in 72%–92% of people with BBS. The complications of obesity, such as high blood pressure (hypertension) and insulin-resistant diabetes mellitus, contribute to kidney disease.

A majority of patients with BBS have extra fingers or toes (polydactyly). They may also have short fingers (brachydactyly) or broad, short feet. Some patients have a combination of all three of these features. Alternately, polydactyly may be limited to one limb, hands only, or feet only. Syndactyly, the fusion of two or more fingers or toes, may

also occur. In some BBS families, all affected members display at least some of these limb abnormalities.

Many individuals with BBS have genital abnormalities. Most boys with BBS have a very small penis, and some also have undescended testes. Men with BBS are usually unable to have children. In women with BBS, the genitalia, ovaries, fallopian tubes, and uterus may be underdeveloped. The vagina may not be completely formed. Though some women with BBS do not menstruate, others menstruate irregularly. Some women are able to have children. In both sexes, there may be birth defects in the urinary or gastrointestinal tract.

Research indicates that people with BBS have characteristic facial features, including a large head with a narrow forehead; short, narrow eye openings; large ears; flat nasal bridge; and a long, smooth area above the upper lip. Teeth are small and crowded. A high, arched palate is common. Still, facial features vary considerably.

Some individuals with BBS have liver disease and poor balance. About half have heart abnormalities.

In addition to the physical effects of the condition, intelligence is often affected. While some BBS patients show normal intelligence, others have mild to moderate learning disabilities. These patients are slower than most children to walk, speak, or reach other developmental milestones. Difficulty with language and comprehension may continue into adulthood. In a few people with BBS, more severe intellectual disability occurs. In some patients, vision handicaps and developmental delay appear to be related.

About a third of children with BBS have behavioral problems that continue into adulthood. These include lack of inhibition and social skills, emotional outbursts, and obsessive–compulsive behavior. Most people with BBS prefer fixed routines and are easily upset by a change in plans.

Diagnosis

Diagnosis of BBS is a challenge for medical professionals. Not only do the symptoms of BBS vary greatly from patient to patient, but some of these symptoms occur in other conditions, many of which are more common than BBS.

The diagnosis is based on clinical features. Genetic testing is available to identify causative mutations but does not rule out a diagnosis. Therefore, patients must have a thorough genetic evaluation. This provides a chance to rule out other disorders with similar symptoms. Some disorders confused with BBS include McKusick-Kaufman syndrome, Alstrom syndrome, Senior-Loken syndrome, Leber congenital amaurosis, and Biemond syndrome type II. McKusick-Kaufman syndrome is

caused by a mutation in the *MKKS* gene that can also be found in people with BBS. While people with this syndrome show some of the same symptoms as BBS patients, the specific *MKKS* mutation differs between the conditions. This explains how one gene can be responsible for two distinct yet similar disorders.

A clinical diagnosis is established when an individual either has four primary clinical features of BBS or three primary and two secondary features. The primary features are retinal degeneration, polydactyly, obesity, learning disabilities, kidney abnormalities, and genital defects (in males). The secondary features are speech delay, developmental delay, behavior problems, eye abnormalities other than retinal degeneration, brachydactyly, syndactyly, poor balance, mild hypertonia, diabetes mellitus, dental abnormalities, cardiovascular abnormalities, or liver problems. To aid in a diagnosis, the patient should receive three particular diagnostic tests. An eye exam called an electroretinogram is used to test the electric currents of the retina. An ultrasound is used to examine the kidneys, as is an intravenous pyelogram (IVP). An IVP is an x-ray assessment of kidney function.

Treatment and management

Treatment and management for those with BBS depends largely on which features of the condition are present. Obesity and kidney disease are major threats. If unchecked, obesity can lead to high blood pressure, diabetes mellitus, and heart disease. Untreated kidney disease can lead to renal failure, a frequent cause of early death in patients with BBS. Some patients require dialysis and kidney transplant. Therefore, it is very important to regularly monitor and manage patients with BBS and to promptly treat any complications. Affected individuals should eat a well-balanced low-calorie diet. They should also exercise regularly. Individuals with BBS should have cardiac, hearing, dental, and neurologic evaluations to detect and treat or manage any problems with these systems.

Because BBS carriers also appear prone to kidney disease, parents and siblings of patients with BBS should take extra precautions. These include baseline screening for kidney defects or cancer, as well as preventive health care on a regular basis.

In order to conserve vision to the extent possible, retinal degeneration should be carefully monitored. Therapy, education, and counselling help prepare the patient for progressive loss of vision. The Foundation Fighting Blindness, a support and referral group, offers help to BBS patients and their families.

Though not life-threatening, learning disabilities and reproductive dysfunction need attention in order to maximize the quality of life for patients with BBS. Affected

QUESTIONS TO ASK YOUR DOCTOR

- Can you tell me the cause of my child's Bardet-Biedl syndrome?
- What are the first treatments or other steps that should be taken to deal with this disorder?
- What long-term medical care will be required for the control of this condition?
- What kinds of symptoms should I watch for that might indicate changes in the progression of this disorder?

people benefit greatly from special or vocational education, speech therapy, social skills training, and community support services. Some adult patients may never be able to live independently and may remain with their families. In these cases, families should plan future living arrangements in case the patients outlive their caregivers.

Genital abnormalities may require hormonal treatment or surgical attention. Sometimes removal of undescended testes is necessary to prevent cancer. Patients with genital and reproductive dysfunction may need counseling to help them deal with the personal, familial, social, and cultural impacts of the condition. The Bardet Biedl Syndrome Foundation and Family Association (<http://www.bardetbiedl.org>) is a support organization for those with the condition and their families. Genetic counseling is available to help fertile BBS patients address their reproductive choices. Affected individuals have a low chance of having an affected child unless their partner also has BBS.

Prognosis

The outlook for people with BBS depends largely on the extent of the birth abnormalities, prompt diagnosis, and follow-up care. Unless they have severe birth defects involving the heart, kidneys, or liver, patients with BBS can have a normal lifespan. There is no treatment for the extensive retinal damage caused by BBS. However, good health care beginning in childhood can help many people with BBS avoid other serious effects of this disorder. Researchers are actively exploring genetic causes, treatment, and management of BBS.

Base editing

Definition

Base editing is a technology that changes a specific DNA base into another. A DNA base is one unit in a DNA sequence. Base editing can be used to fix an error in a DNA sequence. A base editor is a protein that can make this change in the DNA. Prime editing is an updated version of base editing. Currently, base and prime editing are only used in research.

Description

Point mutations are errors in the DNA sequence where one DNA base is substituted for another or inserted or deleted. They are some of the most common causes of genetic disease in humans. A DNA base is one unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T), and cytosine (C). The sequence of these DNA bases is the genetic code and contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid. For example, CGC codes for the amino acid alanine. Proteins are made up of one or more amino acids strung together. The instructions for a particular protein are made up of a number of three-base sequences.

Because DNA is double-stranded, it has two complementary sequences where the bases pair up together. (C) always pairs with (G), and (A) always pairs with (T). One example of a double-stranded DNA sequence for alanine is GCG/CGC. Point mutations can sometimes cause the production of an abnormal protein or even the absence of a protein, which can result in a genetic disease. Around 31,000 point mutations are known to cause genetic diseases. The most common point mutation is the substitution of G–C for A–T.

Base editing can fix point mutations where one DNA base in the sequence is substituted by another. During base editing, the new base is changed back to the original one. Base editing tools are based on CRISPR–Cas technologies. CRISPR–Cas can be used to change an organism's DNA by making a cut in both strands of the DNA at a specific location and tricking the body's DNA repair mechanism to make the desired change. Base editing is a modified version of CRISPR–Cas, which enables the substitution of one DNA base pair for another without causing a double-strand DNA break. Base editing is better at correcting point mutations involving base pair substitutions than traditional CRISPR–Cas. Base editing techniques can fix point mutations almost 10 times more efficiently than traditional CRISPR–Cas technologies and with fewer errors.

There are two types of base editors: cytosine base editors and adenine base editors. Cytosine base editors change the C base in DNA to T, and T to C. Adenine editors change A to G, and G to A.

Base editing cannot fix transversion mutations (A or G) to (T or C) or vice versa. These types of point mutations are less common and usually do not cause a change in the protein or disease. Base editing is also unable to add a missing base pair or sequence of base pairs (deletion) or to remove an extra base pair or sequence of base pairs (insertion).

Prime editing

A new tool called prime editing can overcome some of the limitations of base editing. Prime editing, unlike base editing, can fix transversion mutations and small insertions and deletions. It also has a lower rate of unintentional mutations (0.86%) in other DNA locations than base editing (2.5%). Like base editing, prime editing only nicks one strand rather than cutting both strands.

Similar to CRISPR, both prime and base editing use a Cas enzyme-based editor and a piece of guide RNA, which guides the editor to a location on the DNA that will be changed. Both base and prime editors use the Cas enzyme called CAS9 nickase, which just cuts a strand of the DNA. CRISPR–Cas, on the other

KEY TERMS

Autosomal dominant condition—A disease or condition that results from a mutation in only one copy of a gene pair.

CRISPR–Cas —A tool that is used by researchers to examine and change DNA. CRISPR–Cas can be used to change an organism’s DNA by making a cut in the DNA at a specific location and tricking the body’s DNA repair mechanism to make the desired change. It is based on a tool found naturally in the immune system of bacteria.

Deletion—A mutation where a single base pair or sequence of base pairs is missing.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T), and cytosine (C). The sequence of these bases is the genetic code, which contains the instructions for creating proteins.

DNA sequence—The sequence of DNA bases that contains the instructions for creating proteins.

Enzyme—A type of protein that speeds up chemical reactions in the body.

Insertion—A mutation where there is an extra single base pair or sequence of base pairs.

Point mutation (DNA)—An error in the DNA sequence where one DNA base is substituted for

another or inserted or deleted. This can sometimes cause the production of an abnormal protein or absence of a protein.

Proteins—Large complex biomolecules consisting of chains of amino acids that guide the development and functioning of the body. DNA contains the instructions for creating proteins.

Reverse transcriptase—An enzyme that makes DNA from an RNA template.

Ribonucleic acid (RNA)—The genetic material that is involved in creating proteins. During the creation of proteins, one of the strands of the double stranded DNA sequence is transcribed into single-stranded RNA, which is involved in creating proteins. In the RNA sequence, a base called uracil (U) replaces thymine (T) when it is found in the DNA sequence.

Tissue—A group of cells that have a common function.

Transversion mutation—A point mutation where an (A or G) base is changed to a (T or C) or vice versa.

Transition mutation—A point mutation where an (A) and (G) base are switched or a (C) and (T) base are switched.

hand, uses an enzyme like Cas9, which cuts both of the DNA strands.

DNA base editors include a Cas enzyme to bind to the DNA and a single-stranded DNA-modifying enzyme to make the change in the DNA base. The first cytosine base editor which changes the C base in DNA to T, and T to C, uses a naturally occurring enzyme called APOBEC1, which converts cytosine (C) to uracil (U). Uracil is the base found in RNA that is a complement to the thymine (T) base found in DNA. Adenine editors change A to G, and G to A, using a bacterial enzyme called Tada. Improved base editors are being developed by researchers around the world.

The editor used for prime editing is a fusion of the CAS9 nickase and reverse transcriptase. Reverse transcriptase is an enzyme that makes DNA from an RNA template. The guide RNA used in prime editing is called prime editing guide RNA (pegRNA). It is significantly larger than the standard guide RNA used in CRISPR–Cas. The pegRNA has a sequence of bases that will bind

to the target DNA (PBS) on one end and a template for the goal sequence of bases at its other end. The pegRNA combines with the prime editor to form a complex called the PE:pegRNA complex.

The editing process

Cytosine base editors convert GC to TA or vice versa. With cytosine base editors, the APOBEC1–Cas9 fusion editor is directed by the guide RNA to a target site on the DNA. Cas9 nickase cuts the G-containing strand. APOBEC1 converts cytosine (C) to uracil (U) in the target DNA. The cell has a system that repairs errors in the DNA sequence. This repair system changes uracil, which is not found in DNA, to thymine, which is found in DNA. This results in a GT mismatch, which the repair machinery fixes by converting the guanine to adenine. This ultimately results in an A–T pair.

Adenosine editors work in a similar way to cytosine editors. With adenine editors, Tada, which is fused to CAS9, turns adenosine into a base called inosine (I),

which is not found in the DNA from most species. Inosine is similar to guanine (G), which is normally found in DNA. The cell's DNA repair mechanism changes the inosine to guanine since guanine is the expected base. It then fixes the resulting mismatch of (T) paired to (G) by changing (T) to (C).

During prime editing:

1. The prime editor complex binds to the target DNA.
2. Cas9 cuts one strand of the double-stranded DNA, forming a flap, which exposes a section of the uncut DNA strand and a section of the cut DNA strand.
3. One side of the guide RNA binds to the DNA flap on the nicked DNA strand.
4. A new DNA sequence with the targeted change is transcribed from the RNA sequence on the guide using reverse transcriptase.
5. The newly created DNA sequence joins back with the other strand of DNA that has not been changed.
6. The original DNA sequence that was part of the nicked DNA is removed, leaving one strand with the changes joined to the other strand without the changes.
7. The sequence without the changes can be corrected to match the newly created sequence with the changes, using another guide RNA.

Uses for base and prime editing

Base and prime editing have been used in many different species, such as bacteria, yeast, rice, wheat, zebrafish, mice, rabbits, and monkeys. They have also been used to create animals with specific mutations in order to study genetic diseases and how to treat them. These techniques also have been used on very early human embryos in the lab. The hope is that one day they will be able to treat human diseases.

Base and prime editors have been used to create and fix models of human disease in animals (for example, muscular dystrophy; macular degeneration, an eye disorder that leads to blindness; and progeria, a rare genetic condition that leads to premature aging).

Base editing has also been used to correct mutations associated with cancer and Alzheimer's disease in both animal and human cells in the lab. Mutations that cause hereditary iron overload and sickle cell anemia have also been repaired using base editing. Prime editing has been used to fix sickle cell disease and Tay-Sachs, a childhood enzyme disorder, in human kidney cells.

Base and prime editing can also be used to improve crops to increase their yield or make them more disease resistant. For example, a single base change in the DNA

sequence could help rice plants use nitrogen more effectively and grow better.

Targeting autosomal dominant conditions

Autosomal dominant conditions are diseases that result from a mutation in only one copy of a gene pair. In order to treat some autosomal dominant conditions, the gene with the mutation must be silenced so it stops working. This can be done through base or prime editing. For example, retinitis pigmentosa (RP), an inherited autosomal dominant condition that causes blindness, could theoretically be cured in people who have RP because of a mutation in the P23H gene. By using one of these techniques, the sequence could be changed from CAC to CGC.

Future Uses

Currently, base and prime editing focus on editing DNA. Researchers are working on editors that can fix RNA sequences with mutations. They are also working on editors that might be able to fix mutations in the mitochondria. Mitochondria are energy-producing structures in cells, and they have their own DNA.

Challenges

One of the biggest challenges with base and prime editing is that, like CRISPR-Cas, they can make unintended changes in other parts of the DNA. It can also be challenging to deliver the editing complexes to the target tissue. Current base editors are too large to fit into the systems that are typically used to deliver editing tools to human cells. Researchers are working on making the editors smaller. Some researchers have solved the problem by splitting up the editor and delivering each piece separately.

Summary

CRISPR-Cas, base editing, and prime editing each work best in certain situations. CRISPR-Cas is best for adding or deleting large sequences of DNA. Base editing is best for fixing point mutations, since it has higher efficiency and causes fewer unintentional insertions and deletions. Prime editors are best when flexibility is needed; they offer the option to create insertions, deletions, point mutations, or a combination.

Beare-Stevenson cutis gyrata syndrome

Definition

Beare-Stevenson cutis gyrata syndrome is a serious, extremely rare genetic disorder affecting the skin, skull, genitals, navel, and anus. This condition often results in early death.

Description

Beare-Stevenson cutis gyrata syndrome is also known as Beare-Stevenson syndrome and cutis gyrata syndrome of Beare and Stevenson. This very rare inherited disease causes serious physical problems affecting many body parts. Cutis gyrata is characterized by an unusual ridging pattern in the skin

KEY TERMS

Acanthosis nigricans—A skin condition characterized by darkly pigmented areas of velvety wart-like growths. Acanthosis nigricans usually affects the skin of the armpits, neck, and groin.

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal—Relating to any chromosome besides the X and Y sex chromosomes. Human cells contain 22 pairs of autosomes and one pair of sex chromosomes.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

de novo—A new mutation in a gene that is not inherited from either parent.

resembling corrugation in cardboard. This skin corrugation is present from birth and commonly occurs on the head and arms.

All people with Beare-Stevenson cutis gyrata syndrome have intellectual disabilities. The brain, skull, face, respiratory system, and genitals are often malformed. Death at an early age is common.

Genetic profile

Beare-Stevenson cutis gyrata syndrome is an autosomal dominant disorder, meaning that a person needs a change, or mutation, in only one of two copies of the gene involved to manifest the disorder. As of 2015, all reported cases of Beare-Stevenson syndrome have been due to *de novo* mutations (also called pathogenic variants). *De novo* mutations are changes or variations of the genetic code that occur only in the egg or sperm that become the affected individual; thus, they are genetic but not inherited. All cases of Beare-Stevenson to date have occurred in individuals with no family history of the

disease. This syndrome is associated with mutations (pathogenic variants) in *FGFR2*, a fibroblast growth factor receptor gene. The fibroblast growth factor receptor genes serve as blueprints for proteins important to the inhibition of cell growth during and after embryonic development. *FGFR2* is located on human chromosome 10 in an area designated as 10q26. There are several *FGFR* genes associated with genetic syndromes with craniosynostosis: *FGFR1*, *FGFR2*, and *FGFR3*.

Demographics

Beare-Stevenson syndrome is an extremely rare disorder. Both males and females are affected. The few cases documented in the medical literature (about 25 cases as of 2021) suggest that some cases of this disease might be associated with advanced paternal age. The affected children had older fathers.

Signs and symptoms

A cloverleaf-shaped skull is a very unusual birth abnormality that is common in infants with Beare-Stevenson cutis gyrata syndrome. Abnormalities in skull shape happen when some skull sutures (open seams

between the bony plates that form the skull) fuse before they typically would. Premature closure of the skull sutures is known as craniosynostosis. Growth of the brain pushes outward on skull plates that have not yet fused, causing characteristic bulges in those areas.

The face of someone with Beare-Stevenson cutis gyrata syndrome typically has prominent, bulging eyes that slant downward with droopy eyelids. The middle third of the face is underdeveloped and may appear somewhat flattened. The ears are positioned lower and rotated backward from where they would typically be. Skin ridges may be found in front of the ear. Infants with this condition may be born with teeth.

All people with Beare-Stevenson cutis gyrata syndrome have intellectual disabilities regardless of the degree of craniosynostosis. There may be excess fluid on the brain (hydrocephalus). Additionally, the nerve connection between the two halves of the brain (the corpus callosum) may be absent or underdeveloped.

The most recognizable physical symptom of this syndrome is the unusual ridging, or corrugation, of the skin. This cutis gyrata, usually evident at birth, affects the skin on the scalp, face, ears, lips, and limbs. Patches

Beare-Stevenson cutis gyrata syndrome: pedigree analysis chart (Gale)

QUESTIONS TO ASK YOUR DOCTOR

- What is the probability that a family that has one child with Beare-Stevenson cutis gyrata syndrome is likely to have a second child with the same condition?
- Do children with this condition usually survive infancy?
- What is the possible life expectancy?
- Are there prenatal tests for Beare-Stevenson cutis gyrata syndrome?
- Is there currently any research on this genetic disorder?
- How can I learn more about it?

of skin on the armpits, neck, and groin may also display acanthosis nigricans—unusually dark, thickened patches of skin with multiple delicate growths. Skin tags may be present on the surface of the skin and on the tissues lining the mouth. Affected children usually have a prominent navel and may have extra nipples.

People with this disorder may not be able to fully straighten their arms at the elbow. The skin of the palms of the hands and the soles of the feet often show deep ridging. Affected individuals may have small, underdeveloped fingernails.

Children with Beare-Stevenson cutis gyrata syndrome may have breathing problems and narrowing of the roof of the mouth (cleft palate). The anus may be positioned more forward than normal. The genitals are often malformed and surrounded by corrugated skin. An abnormal stomach valve may cause feeding problems.

Diagnosis

Diagnosis of Beare-Stevenson cutis gyrata syndrome is based on visible physical characteristics of the disease. As of 2015, the suspected diagnosis can be confirmed by DNA testing of the *FGFR2* gene. DNA testing for Beare-Stevenson syndrome starts with DNA sequencing of the coding regions of the *FGFR2* gene, which will detect differences (mutations) in the DNA base sequence of the gene. If no sequence mutations of the *FGFR2* gene are detected, other genetic testing methodologies may be used to detect deletions and duplications within the *FGFR2* gene. If a causative mutation (pathogenic variant) is identified by DNA testing, prenatal genetic testing can be performed in subsequent pregnancies. DNA testing may also

be done prenatally if the diagnosis of Beare-Stevenson cutis gyrata is suspected in an unborn fetus with the characteristic features, like a cloverleaf skull, visible on prenatal ultrasound.

Treatment and management

There is no cure for Beare-Stevenson cutis gyrata syndrome. Of the cases reported in the literature, many died early in life. So few people have been diagnosed with this disease that there is no published information regarding its treatment and management.

Prognosis

Early death is common in people with Beare-Stevenson cutis gyrata syndrome, especially among those with a cloverleaf skull.

Beckwith-Wiedemann syndrome

Definition

Beckwith-Wiedemann syndrome (BWS) is a disorder of overgrowth. This condition is usually characterized by large body size (macrosomia), large tongue (macroglossia), enlarged internal organs (visceromegaly), the presence of an abdominal wall defect (umbilical hernia or omphalocele), and low blood sugar in the newborn period (neonatal hypoglycemia).

Description

Beckwith and Wiedemann initially described BWS in the 1960s. It is also known as Wiedemann-Beckwith syndrome and exomphalos macroglossia gigantism (EMG) syndrome.

BWS syndrome will frequently present prenatally with fetal macrosomia, enlarged placentas, and excessive amniotic fluid (polyhydramnios) that may lead to premature delivery (a baby being born more than three weeks before its due date). In the first half of pregnancy, the majority of amniotic fluid is made by the movement of sodium, chloride, and water, which cross the amniotic membrane and fetal skin to surround the fetus. During the second half of pregnancy, the majority of amniotic fluid is fetal urine that is produced by the fetal kidneys. Another major source of amniotic fluid is secretion from the fetal respiratory tract. This sterile fluid is not stagnant. It is swallowed and urinated by the fetus constantly and is completely turned over at least once a day. If the fetus has an enlarged tongue (macroglossia) and cannot swallow as usual, this can lead to buildup of excess amniotic fluid. Aside from swallowing difficulties in the newborn, macroglossia can also lead to difficulties with feeding and breathing.

Approximately 75% of infants who have BWS will have an omphalocele. An omphalocele occurs when the absence of abdominal muscles allows the abdominal contents to protrude through the opening in the abdomen. This is covered by a membrane into which the umbilical cord inserts. Omphaloceles are thought to be caused by a disruption of the process of normal body infolding at three to four weeks of fetal development. Although 25% of infants with BWS do not have omphaloceles, they may have other abdominal wall defects such as an umbilical hernia or even a less severe separation of the abdominal muscles called diastasis recti.

Fifty to sixty percent of newborns with BWS have low blood sugar levels within the first few days of life. This is called neonatal hypoglycemia and is caused by

having more than the usual number of islet cells in the pancreas (pancreatic islet cell hyperplasia). The islet cells of the pancreas produce insulin. This cluster of cells is called the islets of Langerhans and makes up about 1%–2% of the pancreas. These cells are the most important sugar (glucose) sensing cells in the body. When an individual eats a meal high in glucose or carbohydrates, this leads to a rise in blood sugar, which is then a signal for the increased insulin secretion by the islet cells of the pancreas. If too much insulin is produced, then the blood glucose levels drop too low. This is called hypoglycemia. Glucose is the primary fuel for brain function, so if hypoglycemia lasts too long, it can lead to brain damage. For this reason, detection and treatment of the hypoglycemia is extremely important. Any child born with features of this syndrome should be carefully monitored for hypoglycemia, especially during the first week of life. Occasionally, onset of hypoglycemia is delayed until the first month after birth. For this reason, the parents of a child with BWS should be taught to watch for the symptoms of hypoglycemia so that they can seek care as soon as possible.

Children with BWS have an increased risk of mortality associated with tumor development. These tumors begin development during fetal life (embryonal tumors). These malignant tumors develop in approximately 8% of children who have BWS. The most frequently seen tumors in individuals who have BWS include Wilms tumor (nephroblastoma) and hepatoblastomas. Wilms tumor is a tumor that arises in the kidney and consists of several embryonic tissues. Wilms tumor accounts for 80% of all kidney tumors in children. The peak incidence occurs between two and three years of age but can be present from infancy to adulthood.

Hepatoblastomas are tumors that arise in the liver during fetal development and are the most common primary liver tumor in infancy and childhood. A wide variety of other tumors, both malignant and benign, are also seen in individuals who have BWS and include, but are not limited to, nervous system tumors (neuroblastomas), adrenal gland tumors, and tumors that commonly occur in the head and neck (rhabdomyosarcoma). The increased risk for tumors appears to be concentrated in the first eight years of life, consistent with the embryonic nature of these tumors. In patients who have BWS, tumor development is not common after age eight.

Hemihyperplasia of a lower extremity or of the whole half of the body can be present. For example, one leg may be longer than the other leg. If hemihyperplasia is present, it may be recognized at birth and may become more or less obvious as a child grows. The risk of tumor development increases significantly when hemihyperplasia is present. While only 13% of affected individuals

have hemihyperplasia, 40% of those with neoplasms have hyperplasia. Most patients with BWS remain at or above the 95th percentile for length through adolescence. Advanced bone age can be identified on x-ray examination. Growth rate usually slows down at around age seven or eight. After nine years of age, the average weight remains between the 75th and 95th percentile. Although height, weight, skeletal, and dental maturity may be above average for years, growth rate gradually slows down and eventually children reach average height and normal proportions. Puberty occurs at the usual time.

Another feature includes unusual linear grooves within the ear lobes and/or a groove or pit on the top of the outer ear. Facial characteristics may include prominent eyes (exophthalmos), “stork bite” birth marks (telangiectatic nevi) on the upper half of the face, and “port wine stain” birth marks (facial nevus flammeus) on the face.

Genetic profile

The genetics of BWS is complex. Approximately 85% of individuals who have BWS have no family history of BWS and have a normal karyotype. BWS has been shown to specifically involve problems with a defined region on the short arm of chromosome 11 referred to as 11p15. Approximately 20% of BWS patients have paternal uniparental disomy for chromosome 11p15. Uniparental disomy occurs when an individual receives two copies of a chromosome, part of a chromosome, or a gene from one parent, as opposed to receiving one copy from each parent. In this situation, the amount of gene expression can be changed and cause a disease or disorder. Approximately 5%–10% of patients who have no family history and a normal karyotype have a gene change identified near 11p15 called p57(*KIP2*). This gene region, p57(*KIP2*), is a tumor suppressor region, meaning that its presence suppresses tumor development but that the loss of a normally functioning region could lead to tumor development and potentially lead to BWS. The *IGF2* (insulin-like growth factor-2) gene is also in this region. Both uniparental disomy and a gene mutation result in dosage changes of the normal functioning genes, resulting in overexpression and subsequently increased growth and tumor risk. When a gene change in the p57(*KIP2*) region is found in either of the parents of the affected child, the chance for a future child to have BWS could be as high as 50% with each future pregnancy. The remaining 70% of individuals who have BWS, no family history, and a normal karyotype have no identifiable cause for BWS. The chance for other family members to be affected in this case is expected to be low.

Approximately 10%–15% of individuals who have BWS have a positive family history and a normal karyotype. Of these families, up to 50% may have an identifiable

gene change in the p57 region. If a female carries this gene change, then she has a 50% chance with each pregnancy for having a child with BWS. If a male carries the gene change, the chance for having an affected child is increased, but specific risks are not yet available. Up to 50% of individuals with a positive family history and a normal karyotype do not have an identifiable gene change in the p57 region. In this situation, the chance for the parents to have another affected child is as high as 50%.

Approximately 1%–2% of patients with BWS have a detectable chromosomal abnormality. In patients who have a translocation or a duplication of 11p15 detected on their karyotype, the parents’ chromosomes should be analyzed. Depending upon the results of the parents’ chromosome analysis, there could be up to a 50% chance of having an affected child with BWS.

Demographics

As of 2015, the reported incidence for BWS was approximately 1 in 14,000 in the United States, although this is likely to be an underestimate because of undiagnosed cases. Worldwide frequency is estimated at 1 in 13,700 live births in other developed countries. Incidence is also higher in infants produced with in vitro fertilization. No race predilection has been reported.

Signs and symptoms

Major signs or symptoms include macrosomia, macroglossia, abdominal wall defect, visceromegaly, embryonal tumors, hemihyperplasia, ear lobe creases or ear pits, renal abnormalities, and, rarely, cleft palate.

Minor signs and symptoms include polyhydramnios, prematurity, neonatal hypoglycemia, advanced bone age, heart defects, hemangioma, facial nevus flammeus, and the characteristic facial features, which include underdeveloped midface and possible soft-tissue folds under the eyes.

Diagnosis

BWS is diagnosed primarily by the identification of clinical signs and symptoms. Although there is no official diagnostic criteria for BWS, most would agree that a diagnosis requires the presence of three major findings, or at least two major findings and one minor finding. For the purposes of diagnosis, a major finding would also include a family history of BWS.

When considering the diagnosis of BWS, several other syndromes should also be considered (differential diagnosis). These include, but are not limited to, infant of a diabetic mother, Simpson-Golabi-Behmel syndrome, Perlman syndrome, Sotos syndrome, and Costello syndrome.

If a couple has had a child affected with BWS and an identifiable gene change in the p57 region has been identified, or if a chromosome abnormality is detected by chromosome analysis, then prenatal testing through chorionic villus sampling (CVS) or amniocentesis is possible. If this is not possible, then a detailed ultrasound examination could help to reassure parents that the signs and symptoms of BWS are not present (such as omphalocele, macroglossia, and macrosomia). If any of these signs or symptoms are present, and the couple has had a previously affected child, then it would be very likely that the present pregnancy is affected as well.

If a couple has not had a previously affected child and has had an ultrasound examination that identifies an omphalocele, then chromosome analysis should be offered to rule out a chromosome abnormality and to look for the abnormal findings associated with BWS. If chromosome results are normal, BWS is still a possible cause for the ultrasound findings.

Treatment and management

Early treatment of hypoglycemia is important to reduce the risk of central nervous system damage. Most cases of hypoglycemia are mild and will resolve shortly with treatment; however, some cases may be more difficult. Treatment for hypoglycemia may include steroid therapy, which is usually required for only one to four months.

If an infant has an abdominal wall defect, such as an omphalocele, surgery is usually performed soon after birth to repair the defect. For very large omphaloceles, a multi-stage operation is performed. The treatment and management of the omphalocele depends upon the presence of other problems and is very specific to each individual.

A cardiac evaluation is recommended prior to surgery or if a heart defect is suspected by clinical evaluation. Cardiomegaly is frequently present but usually resolves without treatment.

Nonmalignant kidney abnormalities, including renal cysts and hydronephrosis, occur in approximately 25% of patients. A consult with a pediatric nephrologist would be recommended for patients who have structural renal abnormalities, including any evidence of renal calcium deposits on ultrasound examination.

To screen for tumors, a baseline MRI (magnetic resonance imaging) or CT (computed tomography) examination of the abdomen is recommended for individuals believed to have BWS. To screen for Wilms tumor and other embryonal tumors, abdominal ultrasound is recommended. Blood pressure should also be monitored, as approximately 50% of people with Wilms tumors may

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks of gestation. Under ultrasound guidance, a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Hemihyperplasia—A condition in which overdevelopment or excessive growth of one-half of a specific organ or body part on only one side of the body occurs.

Neonatal—The first 28 days after birth.

Nevus flammeus—A flat blood vessel tumor present at birth, also known as a port wine stain.

have associated hypertension. Because tumor development may occur at any time, though usually before eight years of age, the screening recommendations are that abdominal ultrasound be performed every three to six months until eight years of age and then annually until growth is complete. In addition to ultrasound, screening for hepatoblastoma is accomplished by serial measurements of the serum alpha-fetoprotein (AFP) levels during these years as well. Elevated levels of serum AFP are present 80%–90% of the time when a hepatoblastoma is present. Alpha-fetoprotein is a protein produced by the fetal liver. Concentrations of this protein fall rapidly during the first few weeks after birth and reach adult levels by six months of age. These adult levels are approximately 2–20 ng/ml. Thus, the presence of elevated levels in children and adults usually indicates tumor development. Abnormal AFP levels should be followed with an abdominal CT examination looking for evidence of a tumor in the liver.

Surgical removal is the primary treatment for hepatoblastoma; however, in tumors that cannot be removed, chemotherapy is performed.

Treatment for Wilms tumor is often only surgical removal of the tumor; however, in some cases

QUESTIONS TO ASK YOUR DOCTOR

- What types of early treatment are needed for a child born with Beckwith-Wiedemann syndrome?
- What types of complications should we anticipate for a child with Beckwith-Wiedemann syndrome, and how can those complications be treated?
- Given my child's current condition, what is his or her long-term prognosis?

chemotherapy and radiation therapies are necessary, depending upon the stage of disease and the characteristics of the tumor.

Macroglossia may need to be addressed with the possibility of surgery. The large tongue may partially block the respiratory tract and lead to problems such as difficulty breathing and feeding. In most cases, the tongue growth slows over time and eventually the tongue can be accommodated. Dental malocclusion and a prominent jaw are secondary to the macroglossia. In rare cases, surgery to reduce tongue size is needed and is usually performed between two and four years of age.

Clinical trials

Two clinical trials for the treatment of BWS have been sponsored by the National Institutes of Health (NIH). The first study (NCT00773825) evaluated whether children born following assisted reproductive technologies exhibit an increased risk of genomic imprinting defects. The study has concluded, but as of 2015 no results had been published. The second trial (NCT00503893), in the recruitment stage, seeks to characterize the genetic events related to BWS.

Prognosis

After dealing with initial neonatal issues such as hypoglycemia, feeding, and respiratory problems, prognosis is usually good. Infants with BWS syndrome have an approximately 20% mortality rate, although recent studies indicate that it may be lower than 20%. Mortality is mainly because of complications stated above and also includes complications of prematurity and omphalocele. The prognosis with repaired omphalocele is good. The majority of deaths in cases of omphalocele are usually associated with other anomalies or respiratory insufficiency. Respiratory insufficiency can occur in patients

with omphaloceles if the omphalocele is so large that prenatal lung development cannot occur as usual. Respiratory insufficiency can also occur because of prematurity.

Tumor survival rates for Wilms tumor and for hepatoblastoma are as follows. In general, the four-year survival of all patients who have Wilms tumor with favorable histology approaches 90%. For hepatoblastomas, the combination of surgery and chemotherapy has achieved disease-free survival rates of 100% for stage I, 75% for stage II, and 67% for stage III hepatoblastomas.

In children who have BWS, development is usually normal if there is no history of significant, untreated hypoglycemia. After childhood, complications for patients with BWS are uncommon and prognosis is good.

Beta thalassemia

Definition

Beta thalassemia is an inherited disorder that affects the beta globin (protein molecules) chains in human

blood. These chains are required for the synthesis of hemoglobin A (a compound in the blood that carries oxygen to the cells and carbon dioxide away from the cells). A decrease in beta globin chains causes early destruction of the red blood cells. There are four types of the disorder; they range in severity of symptoms.

The thalassemias were first discovered by Thomas Cooley and Pearl Lee in 1975. Early cases of the disease were reported in children of Mediterranean descent. Therefore, the disease was named after the Greek word for sea, *thalassa*.

Description

Beta thalassemia results from a defect in the beta globin gene. Shortly after birth, the body converts from producing fetal hemoglobin (HbF), to producing beta globin chains. Fetal hemoglobin consists of gamma globin chains that pair with alpha globin chains. Beta globin chains pair with alpha globin chains to produce adult hemoglobin (HbA). Because of the decreased amount of beta globin chains in individuals with beta thalassemia, there is an excess of free alpha globin chains. The free alpha globin chains become abnormal components in maturing red blood cells. This process leads to destruction of the red blood cells in the spleen and a decreased number of red blood cells in the body. Individuals with beta thalassemia may continue producing gamma globin chains in an effort to increase the amount of HbF and compensate for the deficiency of HbA.

There are four subtypes of beta thalassemia: minima, minor, intermedia, and major. Beta thalassemia minima and beta thalassemia minor are less severe forms of the disorder and usually asymptomatic. Beta thalassemia minima is known as the silent form of the disorder. There are no major hematologic (blood and blood-forming tissue) abnormalities. The only notable abnormality is the decrease in beta globin production. Beta thalassemia minor is rare. A person with this type of the disorder inherits only one beta globin gene. Although children with beta thalassemia minor are usually asymptomatic, they do have abnormal hematologic (blood-related) findings.

Beta thalassemia intermedia and major often require medical treatment. Beta thalassemia intermedia is usually found during the toddler or preschool years. It is considered to be the mild form of thalassemia major and frequently does not require blood transfusions. Thalassemia major is typically diagnosed during the first year of life. There are two designations for beta thalassemia major: beta zero and beta positive. In beta zero, there is no adult hemoglobin (HbA) present as a result of the very small production of beta globin. In type beta

positive, there is a small amount of detectable HbA. In both forms of beta thalassemia major, individuals will experience severe fatigue due to the decrease or absence of HbA, which is needed to carry oxygen to the cells.

Other names for beta thalassemia include erythroblastic anemia, Mediterranean anemia, microcytemia beta type, and thalassemia beta type. Alternate names associated with beta thalassemia minor include thalassemia minor, minor hereditary leptocytosis, and heterozygous beta thalassemia. Alternate names associated with beta thalassemia intermedia include intermedia Cooley's anemia and thalassemia intermedia. Alternate names associated with beta thalassemia major include Cooley's anemia, erythroblastic anemia of childhood, hemoglobin lepreux syndrome, major hereditary leptocytosis, Mediterranean anemia, microcythemia, target cell anemia, and thalassemia major.

Risk factors

Beta thalassemia is a genetic disease originally found in Mediterranean populations. People of Mediterranean descent are at increased risk of thalassemia.

Demographics

Worldwide, beta thalassemia is a fairly common blood disorder. Beta thalassemia occurs more frequently in people from the Mediterranean area, North Africa, the Middle East, India, Central Asia, and Southeast Asia. Cooley's Anemia Foundation estimates that over 2 million people in the United States carry the genetic trait for thalassemia. The highest incidences occur in Cyprus, Sardinia, and Southeast Asia. As much as 10% of the populations in those areas may have the disorder. Population migrations have led to a global distribution of beta thalassemia, now also common in northern Europe, North and South America, the Caribbean, and Australia.

Signs and symptoms

Beta thalassemia is an autosomal recessive disorder caused by mutations in the *HBB* gene on chromosome 11 at 11p15.4. As of 2015, more than 250 mutations in this gene are known to cause beta thalassemia. In the autosomal recessive pattern, a person who is a carrier will not develop the disorder but may pass on the gene for the disorder to their child. There is a 25% chance for each pregnancy that the disorder will be passed on to the children if both parents are carriers of the trait and a 100% chance if both parents have the trait.

A parent who is a carrier of the beta thalassemia trait and has a child with someone who is a carrier of other abnormal hemoglobins is at risk of having children with blood disorders related to beta thalassemia. If one parent

carries the beta thalassemia trait and the other carries the hemoglobin E trait, their children have a 25% chance of having E beta thalassemia, a moderately severe anemia. Similarly, if one parent carries the beta thalassemia trait and the other parent carries the hemoglobin S trait, the children have a 25% chance of having sickle beta thalassemia, which can be almost as severe as sickle cell disease.

There are, however, a few families in which mutations in the *HBB* gene are transmitted in an autosomal dominant pattern. In the autosomal dominant pattern, only one copy of the mutated gene in each cell is sufficient to produce the symptoms of beta thalassemia.

Individuals with thalassemia minor are carriers of the beta globin gene. Therefore, these individuals possess only one of the genes necessary to express the disorder. These individuals are usually asymptomatic or have very few symptoms.

Individuals with thalassemia major express both abnormal genes for beta globin and therefore will have the disease. These individuals show severe symptoms for the disorder. The beta globin gene is found on chromosome 11. Mutations resulting in beta thalassemia are usually caused by substitutions, although some may be caused by deletions. Mutations involve inappropriate sequence of nucleotides, the building blocks of genes. Substitutions are the switching of one nucleotide for another. Deletions occur when part of a chromosome is missing. Substitutions occur within the nucleotide and deletions occur on the chromosome on which the beta globin gene is found.

Symptoms for beta thalassemia vary in severity according to the subtype of the disorder.

Beta thalassemia minima

There are no symptoms associated with this subtype. It is considered to be a “silent” form of beta thalassemia.

Beta thalassemia minor

Individuals with this type of beta thalassemia may be asymptomatic or experience very few symptoms. Symptoms may be worse in individuals who are pregnant, under stress, or malnourished. Symptoms may include:

- **Fatigue.** This may be the only symptom that an individual with beta thalassemia minor exhibits. Fatigue is caused by the decreased oxygen-carrying capacity of the red blood cells, resulting in lowered oxygenation of cells and tissues.
- **Anemia.** Anemia is a decrease in the amount of hemoglobin in the blood. Hemoglobin is needed to carry oxygen in the red blood cells. In beta thalassemia minor there is a decrease in adult hemoglobin (HbA) and

an increase in hemoglobin A2. Hemoglobin A2 is a minor hemoglobin that contains delta globin chains in the place of beta globin chains. Anemia is most likely to occur during pregnancy.

- **Splenomegaly.** Enlargement of the spleen may occur due to increased removal of defective red blood cells. This symptom is rarely seen in individuals with beta thalassemia minor and may be accompanied by pain in the upper left portion of the abdomen.
- **Pale skin.** The skin color of individuals with beta thalassemia minor may be pale due to oxygen deprivation in blood.

Beta thalassemia intermedia

Individuals with this form of beta thalassemia usually begin to show symptoms during the toddler or preschool years. These individuals present with many of the same symptoms as beta thalassemia major. Symptoms for beta thalassemia intermedia are less severe, however, and may include:

- **Anemia.** In individuals with beta thalassemia intermedia, hemoglobin levels are greater than 7g/dL but are lower than normal. Normal levels for hemoglobin are 13–18 for males and 12–16 for females.
- **Hyperbilirubinemia.** Bilirubin is a yellow pigment of bile that is formed by the breakdown of hemoglobin in the red blood cells. Excessive bilirubin in the blood is caused by the increased destruction of red blood cells (hemolysis) in the spleen.
- **Splenomegaly.** Enlargement of the spleen is caused by increased removal of defective red blood cells. Red blood cells are defective due to the increased amount of inclusion bodies caused by circulation of free alpha globin chains.
- **Hepatomegaly.** Enlargement of the liver may be caused by a build-up of bile due to increased amounts of bilirubin in the blood.
- **Additional abnormalities.** Individuals with beta thalassemia intermedia may have a yellow discoloration (jaundice) of the skin, eyes, and mucous membranes. This discoloration is caused by increased amounts of bilirubin in the blood. Individuals may also suffer from delayed growth and abnormal facial appearance.

Beta thalassemia major

Individuals with this form of beta thalassemia present with symptoms during the first year after birth. Symptoms are severe and may include:

- **Severe anemia.** Individuals with beta thalassemia major suffer from a hemoglobin level of less than 7 mg/dl.

KEY TERMS

Bilirubin—A yellowish pigment derived from the breakdown of heme during the body's clearance of worn-out red blood cells. Bilirubin is responsible for the discolored appearance of bruises, the yellowish discoloration of the skin in jaundice, and the yellow color of urine.

Chelation therapy (pronounced key-LAY-shun)—A form of therapy in which chelating agents are administered to remove heavy metals from the body. Chelating agents are chemicals that have a special affinity for metal ions.

Cholelithiasis—The formation of gallstones within the gallbladder.

Erythroblast—The immediate precursor of a normal red blood cell.

Ferritin—An intracellular protein that stores iron and releases it in a controlled manner. Ferritin in blood plasma is an indirect marker of the total amount of iron stored in the body.

Globins—A family of heme-containing proteins involved in the binding or transporting of oxygen in the body.

Hematopoiesis—The process of blood cell formation from stem cells in the medulla of the bone (bone marrow).

Heme—The iron-containing molecule in hemoglobin that serves as the site of oxygen binding.

Hemoglobin—The protein-iron compound in the blood that carries oxygen to the cells and carries carbon dioxide away from the cells.

Hemoglobin E—An abnormal hemoglobin with a single-point mutation in the beta chain. People who inherit the hemoglobin E gene from one parent and the beta thalassemia gene from the other develop hemoglobin E beta thalassemia, which is a severe disease.

Hemoglobin S—The most common type of abnormal hemoglobin; it is the basis of sickle cell trait and sickle cell anemia.

Hepatomegaly—Abnormal enlargement of the liver.

Medulla—In general, the central portion of a body organ; with regard to bone, the marrow that lies at the center of the long bones. The English word is derived from the Latin word for marrow.

Red blood cells (RBCs)—Hemoglobin-containing blood cells that transport oxygen from the lungs to tissues. In the tissues, the red blood cells exchange their oxygen for carbon dioxide, which is brought back to the lungs to be exhaled.

Spherocyte—A red blood cell that has an abnormal spherical shape rather than the normal shape of a concave disk.

Splenomegaly—Abnormal enlargement of the spleen.

- **Hyperbilirubinemia.** Individuals will have an increased amount of bilirubin in the blood, resulting from the increased destruction of red blood cells (hemolysis) by the spleen.
- **Jaundice.** Individuals may experience a yellow discoloration of the skin, eyes, and mucous membranes caused by increased amounts of bilirubin in the blood.
- **Extramedullary hematopoiesis.** Abnormal formation of red blood cells outside the bone marrow may occur in the body's attempt to compensate for decreased production of mature red blood cells. This abnormal formation can cause masses or the enlargement of organs, which may be felt during physical examination.
- **Splenomegaly.** Enlargement of the spleen may result due to increased destruction of red blood cells and the occurrence of extramedullary hematopoiesis.
- **Hepatomegaly.** Enlargement of the liver may result due to accumulation of bile or the occurrence of extramedullary hematopoiesis.
- **Cholelithiasis.** Cholelithiasis is the presence of stones in the gallbladder, which may lead to blockage and cause bile to be pushed back into the liver.
- **Bone marrow expansion.** The bone marrow becomes expanded due to the increase of the production of red blood cells (erythropoiesis) in an attempt to produce more mature red blood cells and decrease the anemic state of the body.
- **Facial changes.** Due to expansion of the bone marrow, children will develop prominent cheekbones, depression of the nasal bridge, and protrusion of the upper jaw. These facial changes are a classic sign in children with untreated beta thalassemia.
- **Iron overload.** Iron overload of the tissues can be fatal and is due to erythroid (red blood cell) expansion. The increased destruction of a vast amount of red blood cells causes increased amounts of iron to be released from the hemoglobin.

- Cardiovascular abnormalities. Accumulation of iron deposits in the heart muscle can lead to cardiac abnormalities and possibly cardiac failure.
- Delayed puberty in adolescents.
- Additional abnormalities. Individuals may also suffer from pale skin, fatigue, poor feeding, failure to thrive, and stunted growth.

Symptoms of beta thalassemia minor may be similar to those of sideroblastic anemia and sickle cell disease. Sideroblastic anemia is a disorder characterized by low levels of hemoglobin, fatigue, and weakness. Sickle cell disease is a disease that changes the red blood cell shape, rendering it incapable of functioning.

Symptoms of beta thalassemia major may be similar to those of hereditary spherocytic hemolytic anemia (presence of sphere-shaped red blood cells).

Diagnosis

Completing a family history, performing a complete physical examination, and analyzing results of blood (hematological) tests can lead to a diagnosis of beta thalassemia.

Examination

Bone abnormalities and masses or enlarged organs may be recognized during physical examination. In addition, the doctor may note that the patient has some of the facial features associated with beta thalassemia.

Tests

Blood tests are performed to establish diagnosis. These include complete blood count (CBC), blood smear, iron studies, blood protein analysis, and a hemoglobinopathy test. The goal of the iron studies is to determine whether there is iron deficiency. The goal of the hemoglobinopathy test is to measure the type and relative amounts of hemoglobin present in the red blood cells. Genetic testing can also be used to investigate deletions and mutations in the alpha and beta globin producing genes. Other genetic tests include linkage analysis, sequence analysis of the entire coding region, and sequence analysis of select exons.

Normal hemoglobin results are 13–18 g/dL for males and 12–16 g/dL for women. Normal red blood cell counts are 4.7–6.1 million for males and 4.2–5.4 million for females. In individuals with the beta zero form of beta thalassemia major, there will be no HbA present in the blood.

Prenatal testing to detect beta thalassemia can be done by completing an amniocentesis (obtaining a sample of amniotic fluid, which surrounds the fetus during pregnancy). Lab results will vary depending on the type of beta thalassemia that an individual might have.

Treatment and management

Traditional

Beta thalassemia minima and minor usually require no treatment. Pregnant women who suffer from beta thalassemia minor may require blood transfusions to keep hemoglobin levels normal. Individuals with beta thalassemia intermedia and major can be treated with blood transfusions and iron chelation (binding and isolation of metal) therapy. Although individuals with beta thalassemia intermedia do not usually require transfusions, in certain cases they may be necessary.

Blood transfusions are performed in individuals that present with severe symptoms such as anemia and impaired growth and development. Children may receive transfusions every four to six weeks. A high risk associated with transfusions is iron overload, which is fatal. Iron overload results from inadequate amounts of serum transferrin needed to bind and detoxify iron. Iron accumulation can lead to dysfunction of the heart, liver, and endocrine glands.

Monitoring iron levels in the body is essential. Individuals receiving blood transfusions should keep total body iron levels at 3–7 mg of iron per gram of body weight. Methods to measure iron levels include a serum ferritin test, liver biopsy, and radiological study performed by a Superconducting Quantum Interference Device (SQUID).

The serum ferritin (iron storage protein) test is completed by testing a blood sample for ferritin content. This method is the easiest and most affordable way of testing for body content of iron, but it is not fully reliable. A liver biopsy is an invasive procedure that requires removal of a small piece of the liver. Still, studies have shown that a liver biopsy is very accurate in measuring the level of iron stores in the body. The third method, which requires a SQUID, is also very accurate in measuring iron stores. The SQUID is a highly specialized machine and few centers in the world possess this advanced technology.

Individuals receiving blood transfusions should pay close attention to iron intake in the diet. It is recommended that children under age 10 keep dietary iron intake at 10 mg/day or less. Individuals age 11 or older should keep dietary iron intake at 18 mg/day or less. Foods high in iron include beef, beans, liver, pork, peanut butter, infant cereal, cream of wheat, prunes, spinach, raisins, and leafy green vegetables. Individuals should read food labels and avoid using cast iron cookware, which can provide more iron in food during cooking. Increased amounts of iron in the body can cause a decrease in calcium levels, which impairs organs that aid in building strong bones. Individuals with beta thalassemia major

are at risk of developing osteoporosis (loss of bone mass resulting in weakened bones). Males with thalassemia major are at greater risk than females. Increased dietary intake of calcium and vitamin D can help increase the storage of calcium in the bones, thus making the bones stronger and decreasing the risk of osteoporosis. Treatment with bisphosphonates is an increasingly common therapy for children with beta thalassemia at risk of osteoporosis.

Surgery

In some cases (most often thalassemia major), the doctor may recommend splenectomy (surgical removal of the spleen) to lower the need for transfusions and the associated risk of iron overload. Patients with thalassemia minor may require cholecystectomy (surgical removal of the gallbladder) if large numbers of gallstones are formed in the gallbladder.

Drugs

Iron overload can be prevented with the use of iron chelating therapy. Chelating agents attract the excess iron and assist with the process of binding and detoxifying this iron in the body. The drug deferoxamine (Desferol) is one of the most widely used iron chelating agents. Treatment is completed through nightly infusions of deferoxamine by a pump or with daily intramuscular injections. Infusion by pump is used for the administration of high doses. Low doses are given through injections. Another iron chelating agent, deferiprone (Ferriprox), was approved by the Food and Drug Administration (FDA) in 2011 for the treatment of transfusion-related iron overload in thalassemia patients when deferoxamine treatment is inadequate. Unlike deferoxamine, deferiprone is given by mouth.

Still another orally administered chelating agent is deferasirox (Exjade, Desirox), originally approved by the FDA in 2005 to treat transfusion-related iron overload, and approved by the FDA in 2013 for a new indication, namely the treatment of non-transfusion-related iron overload in patients with thalassemia. Some physicians report that combination chelation therapy, either deferiprone and deferasirox or deferasirox and deferoxamine, yields better results than any of the chelating agents given alone.

Researchers are investigating the use of the drugs hydroxyurea and butyrate compounds to increase the amounts of fetal and total hemoglobin in individuals with beta thalassemia. Other drugs under investigation include demethylating agents (decitabine and 5-azacytidine), histone deacetylase inhibitors (vorinostat and panobinostat), and a derivative of thalidomide known as pomalidomide.

QUESTIONS TO ASK YOUR DOCTOR

- Which subtype of beta thalassemia do I have?
- What are the treatment options?
- Where can I find information about the medications used to treat beta thalassemia?
- What kind of information will the tests provide?
- How does the condition affect quality of life?
- Should genetic testing be performed?

Alternative

Bone marrow transplantation is another form of treatment for beta thalassemia. Outcomes of transplantation are greatly influenced by the health of the individual. This form of treatment is only possible when the individual has a suitable donor.

Studies using gene therapy, such as stem cell replacement, genome editing technologies, and viral vectors are also being conducted.

Clinical trials for the treatment of beta thalassemia are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2021, the NIH reported 190 ongoing or recently completed studies in the United States. Most are studies of currently approved or investigational chelating agents. Still, some are trials of cord blood, gene therapy, or bone marrow transplantation as therapies for beta thalassemia. Clinical trial information is constantly updated by the NIH. The most recent information on beta thalassemia trials can be found on the Clinical Trials website at <https://clinicaltrials.gov>

Prevention

Beta thalassemia cannot be prevented because it is an inherited disease. Preventive research is currently investigating prenatal and newborn interventions.

Prognosis

Prognosis for beta thalassemia is good for individuals diagnosed early and those who receive proper treatment. Children with beta thalassemia major live 20–30 years longer with treatment by blood transfusions and iron chelation therapy. On the other hand, transfusion therapy is not risk-free. A study sponsored by the Centers for Disease Control and Prevention (CDC) reported in 2014 that 48% of the 407 patients who were followed had allergic or hemolytic reactions to transfusions; 24% were exposed to infectious organisms through transfusions; and other patients had organ dysfunction due to

iron overload in spite of chelation therapy. The most common causes of mortality in persons with beta thalassemia are anemia and iron overload.

Bicuspid aortic valve

Definition

Bicuspid aortic valve is the most common malformation of the heart valves. In this type of deformity, the aortic valve has only two cusps, which are rigid points such as those seen on leaves, instead of the three cusps normally present. This condition may lead to abnormalities in the flow of blood from the heart to the aorta, leading to changes in the function of the heart and lungs. Treatment consists of surgical repair or replacement of the valve.

Description

A valve is a device that allows a fluid to flow in only one direction in a defined path, thereby preventing backflow of the fluid. The heart has four such valves, which allow the blood to flow in an orderly pattern through each of the four chambers of the heart and out into the largest artery of the body, the aorta. The aorta in turn branches into other blood vessels in the neck, limbs, and organs of the body to supply it with oxygenated blood.

The aortic valve divides the left ventricle of the heart and the aorta. It is the last valve before blood leaves the heart and passes into the aorta. The valve is formed during pregnancy and is normally composed of three separate cusps or leaflets, which, when closed, form a tightly sealed barrier that prevents backflow of blood from the aorta into the heart. Thus, when the heart contracts or pumps, the aortic valve opens and allows blood to pass from the heart into the aorta, and when the heart relaxes, the aortic valve closes and prevents backflow of blood from the aorta into the heart.

The three-cusp structure of the valve is essential for its proper function and was noted as far back as the fifteenth century, when the great master of the High Renaissance, Leonardo da Vinci, reported on his observations of anatomy and blood circulation. In bicuspid aortic valve, the aortic valve fails to form properly during development in the womb; for reasons that are unclear, two of the three cusps fail to separate properly and remain attached along one edge, resulting in an aortic valve with only two cusps.

Bicuspid aortic valve is the most common heart valve defect at birth, and many people live a normal life without even being aware of this condition. Unfortunately, bicuspid aortic valves are also more prone to disease than the normal three-cusped valves. Over the years, conditions such as restricted blood flow to the aorta (aortic stenosis), backflow of blood from the aorta into the heart (aortic regurgitation, or aortic insufficiency), and valve infection (endocarditis) are often detected with associated symptoms during the adult years as progressive damage is done to the bicuspid aortic valve.

Illustration of a normal heart valve (left) and one with a valve defect. (Alila Medical Media/Shutterstock)

Other conditions that may occur with bicuspid aortic valve include aneurysm of the aorta (ballooning of the aorta wall) and aortic dissection (a life-threatening split in the layers of the aorta).

Genetic profile

Most occurrences of bicuspid aortic valve appear to be sporadic (i.e., random and not associated with an inherited defect) and are not passed on from parent to

child. However, there have been some reports that the valve malformation appears in multiple members of the same family and is associated with a mutation in the *NOTCH1* gene. In at least one report, this familial occurrence appears to be inherited in an autosomal dominant pattern with reduced penetrance (not showing the malformation despite possessing the genetic cause for it). For purposes of genetic counseling, bicuspid aortic valve can be regarded as a sporadic condition with an extremely low risk of being transmitted from parent to child.

Demographics

Bicuspid aortic valve is underdiagnosed but may be present in as many as 1%–2% of the population in the United States. Bicuspid aortic valve is more common among males than females, with lower than expected prevalence in African-Americans.

Risk factors

Risk factors for bicuspid aortic valve include the presence of such other genetic syndromes as Turner syndrome, Down syndrome, velocardiofacial syndrome, and Loeys-Dietz syndrome.

Signs and symptoms

Many people with bicuspid aortic valve experience no symptoms and may live their entire lives unaware of the condition. However, progressive damage or infection of the valve may lead to three serious conditions: aortic stenosis, aortic regurgitation, or endocarditis.

As a person ages, calcium deposits form on a bicuspid aortic valve, making it stiff. Eventually, the valve may become so stiff that it does not open properly, making it more difficult for blood to leave the heart and pass into the aorta, resulting in aortic stenosis. When this blockage becomes serious enough, people may experience shortness of breath, chest pain, or fainting spells. These symptoms usually begin between the ages of 50 and 60 years old. Eventually, the blockage can become so bad that blood backs up in the heart and lungs instead of going out to supply the rest of the body with oxygen (congestive heart failure). Additionally, this condition can lead to thickening of the heart wall, which may cause abnormal heart rhythms leading to sudden death.

Aortic regurgitation results when the valve fails to close properly. People who develop this condition may become short of breath when exerting themselves. The extent of symptoms experienced by the patient depends on the severity of the aortic regurgitation.

Finally, bacteria may deposit on the malformed bicuspid aortic valve, causing endocarditis. People with endocarditis may have symptoms of lingering fevers, fatigue, weight loss, and sometimes damage to the kidneys or spots on their fingers and hands.

Other dangerous conditions associated with bicuspid aortic valve include aortic aneurysm and aortic dissection. People with aortic aneurysms usually do not experience symptoms unless the aneurysm ruptures, but people with aortic dissection experience tearing back pain. Aortic aneurysm rupture and aortic dissection are very dangerous and can rapidly lead to death if not promptly treated.

Diagnosis

Any of the symptoms of aortic stenosis, aortic regurgitation, or endocarditis should prompt a search for an underlying malformation of the aortic valve. Aortic stenosis or regurgitation is diagnosed by a combination of physical exam and cardiovascular tests and imaging.

Examination

The earliest sign of aortic valve problems is a murmur (the sound of abnormal patterns of blood flow) heard with a stethoscope. When the valve has high levels of calcium deposits, a characteristic clicking sound can also be heard with the stethoscope just as the stiff valve attempts to open.

Tests

If these signs are present on examination, it suggests that the aortic valve may be damaged. Tests can then be performed, such as magnetic resonance imaging (MRI) or echocardiography, a method that uses ultrasound waves to look at the aortic valve, similar to the way in which ultrasound is used to look at a fetus during pregnancy. Often, only two cusps are seen on the aortic valve during the echocardiography, confirming a diagnosis of bicuspid aortic valve.

Endocarditis is diagnosed by demonstrating the presence of bacteria in the bloodstream. This is performed by taking blood from the patient and growing the bacteria on plates with specialized nutrients. Skilled technicians can then use different tests to identify which species of bacteria is present so that appropriate treatment can be started. The diagnosis of endocarditis is also confirmed by using echocardiography to look for bacterial growths on the aortic valve. During the echocardiography, a bicuspid valve is often seen and explains the tendency to develop endocarditis.

Treatment and management

Most people with bicuspid aortic valve will not experience any complications or symptoms and will not require treatment. However, in patients with any complication of valve damage, treatment may be necessary.

Traditional

In younger patients who have aortic stenosis, a procedure can be performed in which a small balloon is inserted through one of the major blood vessels and into the aortic valve. The balloon is then inflated, creating a bigger opening for blood to pass. Alternatively, an “open

QUESTIONS TO ASK YOUR DOCTOR

- Should I restrict my level of physical activity?
- What are the possible complications of bicuspid aortic valve?
- Is surgery required?
- What are the treatment options?

heart" procedure can be performed to cut the valve into a more normal configuration. These treatments are usually temporary, and later in life the patient, as well as any adult with advanced aortic stenosis, will most likely require aortic valve replacement.

Valve replacement is an open heart operation in which the original malformed valve is removed and replaced with a new valve. This new valve can come from a human donor who has died, from cows or pigs, or even from another part of the patient's heart. These valves function well but may need to be replaced after 10 to 20 years, as they wear out. Another option is to use an artificial valve made of metal, plastic, or cloth. However, people who receive these artificial valves need to take blood thinners every day in order to prevent blood clots from forming on the new valve.

People who have been identified as having bicuspid aortic valve are followed regularly by a cardiologist, with possible consultation with a cardiothoracic surgeon. The function of the bicuspid aortic valve is monitored with echocardiography, and the state of the heart itself is followed by regular electrocardiograms.

It should be noted that children with aortic stenosis may not be able to engage in vigorous physical activity without the risk of cardiac arrest and should consult with their physician. In addition, all people with bicuspid aortic valve should receive antibiotics prior to any dental procedure or surgery; these procedures may allow bacteria to enter the bloodstream and could result in endocarditis if antibiotics are not given beforehand.

Drugs

Patients with endocarditis need to be hospitalized and treated with high doses of antibiotics given through a vein for several weeks. Damage done to the valve by the bacteria may make it necessary for a valve replacement procedure to be performed after the patient has recovered from the infection.

Prevention

Bicuspid aortic valves run in some families and the condition cannot be prevented.

Prognosis

Most people born with bicuspid aortic valve experience no symptoms or complications, and their lives do not differ from someone born with a normal aortic valve. In patients who do experience complications and require valve replacement, risks of the operation generally depend on age, general health, specific medical conditions, and heart function. It is better to perform the operation before any of the advanced symptoms (shortness of breath, chest pain, fainting spells) develop; in patients without advanced symptoms, the risk of a bad outcome of surgery is only 4%. If a person with advanced symptoms chooses not to undergo surgery, the risk of death within three years is more than 50%. In general, valve replacement greatly reduces the amount and severity of symptoms and allows patients to return to their normal daily activities without discomfort after they recover from the surgery.

Biotinidase deficiency

Definition

Biotinidase deficiency is a rare inherited defect in the body's ability to use dietary biotin, one of the B vitamins. The disease is also known as juvenile or late-onset multiple carboxylase deficiency. The milder form of this disorder, partial biotinidase deficiency, if left untreated, may cause muscle weakness (hypotonia), hair loss (alopecia), and skin rashes. The most severe form can cause additional symptoms including fungal infections, breathing problems, vision and hearing loss, impaired movement and balance (ataxia), and developmental delays in children. Symptoms may be improved or prevented by appropriate treatment.

Description

Biotin is essential as a co-factor (co-enzyme) for the reactions of four enzymes called carboxylases. These enzymes, in turn, play important roles in the metabolism of sugars, fats, and proteins within the human body. Another key enzyme, biotinidase, recycles biotin from these reactions so it can be used again. A defect in the biotinidase gene results in decreased amounts of normal enzyme, and prevents the reuse of biotin. The decreased

level of biotin leads to a disruption of the function of the four carboxylases that depend on biotin and results in a variety of abnormalities of the nervous system and skin. Since symptoms usually do not appear immediately at birth, biotinidase deficiency is also referred to as late-onset or juvenile multiple carboxylase deficiency. A related disorder, early-onset or neonatal multiple carboxylase deficiency, is caused by the lack of a different enzyme, holocarboxylase synthetase. As the name suggests, this deficiency results in symptoms in the newborn period.

Genetic profile

Inheritance pattern

Biotinidase deficiency is an autosomal recessive disorder affecting both males and females. It is caused by mutations in the *BTBD* gene, which is responsible for production of the enzyme biotinidase. In individuals with this disorder, both copies of the *BTBD* gene are defective. Both parents of an affected child have one abnormal copy of the gene but usually do not show symptoms because they also have one normal copy. The normal copy provides approximately 50% of the usual enzyme activity, a level adequate for the body's needs. Individuals with one abnormal copy of the gene and 50% enzyme activity are

Biotinidase deficiency: pedigree analysis chart (Gale)

said to be carriers or heterozygotes. As is typical of autosomal recessive inheritance, their risk for having another child with the disorder is 25% in each subsequent pregnancy.

Gene location

The *BDT* gene for biotinidase production is located on the short arm of chromosome 3 (3p25). More than 150 different mutations in this gene have been identified in individuals with biotinidase deficiency. Most *BDT* gene mutations cause profound biotinidase deficiency. This severe form of the disorder results when the activity of biotinidase is reduced to less than 10% of normal. The fact that there are many different types of mutations helps explain why symptoms are variable from one individual to another. However, the presence of variability even within a family suggests there may be other, as yet unknown, factors that affect the severity of the disease.

Demographics

Individuals with biotinidase deficiency have been described in various ethnic groups worldwide. In the general population, the incidence of the disease is estimated at about 1 in 60,000 individuals; 1 in every 123 individuals is a carrier.

Signs and symptoms

The onset of symptoms is typically between three and six months of age but varies widely from one week to several years. The most common clinical features are hair loss (alopecia), skin rash (dermatitis), seizures (convulsions), decreased muscle tone (hypotonia), difficulty walking (ataxia), breathing problems, redness of the eyes (conjunctivitis), hearing and vision loss, and developmental delay. Children with biotinidase deficiency are prone to fungal and bacterial infections, suggesting that the immune system is also affected. Symptoms are highly variable among affected individuals, even within a single family.

Biotinidase deficiency is classified as either partial or profound. If there is at least 10% enzyme activity, the deficiency is considered partial and is usually associated with minimal to mild symptoms. Profound biotinidase deficiency, defined as less than 10% of normal activity, is characterized by many of the symptoms mentioned above, and can result in coma and death if left untreated.

Diagnosis

Children with profound biotinidase deficiency may show general signs such as vomiting, seizures, and low muscle tone, all of which can be associated with a number of different disorders. Diagnosis can be difficult because

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal recessive—A pattern of genetic inheritance where two abnormal genes are needed to display the trait or disease.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Co-enzyme—A small molecule such as a vitamin that works together with an enzyme to direct a biochemical reaction within the body.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Gene—A building block of inheritance containing the instructions for the production of a particular protein and consisting of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Immune system—A major system of the body that produces specialized cells and substances that interact with and destroy foreign antigens that invade the body.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual and can be transmitted to offspring. The change may manifest as a disease.

of the many different enzyme deficiencies (inborn errors of metabolism) with similar symptoms and test results. For example, abnormally high amounts of certain acidic products in the blood and urine can be typical of a number of different metabolic disorders including biotinidase deficiency. Accurate diagnosis is made by measuring the activity of the enzyme in blood or skin cells. A number of states and countries test for this disorder at birth as part of a comprehensive newborn screening program. Infants whose tests indicate they have biotinidase deficiency can be started on treatment before symptoms appear. With regular treatment these infants usually remain free of any symptoms.

QUESTIONS TO ASK YOUR DOCTOR

- What is biotinidase? How is it involved in my child's biotinidase deficiency condition?
- Our first child was born with biotinidase deficiency disorder. What is the probability that later children may have the same condition?
- Where can we get more detailed information about the genetic basis of this disorder?
- I understand that biotin supplementation may reverse many early symptoms of biotinidase deficiency disorder. Which symptoms are affected by this treatment, and which are not?

Carrier testing

Most carriers can be detected by measuring biotinidase activity in their blood. Fifty percent of normal enzyme activity is characteristic of carriers. Specific DNA tests can usually detect the particular gene mutation in any affected individual or carrier.

Prenatal diagnosis

If a couple has had one child with biotinidase deficiency, they can be offered prenatal testing in future pregnancies. Prenatal testing is accomplished by measuring biotinidase activity in amniotic fluid cells obtained by amniocentesis around the 16th week of pregnancy. Alternately, if specific gene mutations have been identified in the parents, fetal DNA from amniotic fluid cells can be studied to test for these same mutations in the fetus. Carrier couples who are considering prenatal diagnosis should discuss the risks and benefits of this type of testing with a geneticist or genetic counselor.

Treatment and management

Treatment of the profound form of biotinidase deficiency consists of giving large doses of biotin orally. Partial deficiencies are usually treated with lower doses. The biotin must be in a free form; that is, not attached to other molecules, as would be the case with the biotin found in food. Properly treated, biotinidase deficiency is not a life-threatening condition. Still, biotin treatment must continue throughout life. No treatment is needed before birth because the developing fetus is provided with sufficient free biotin from the mother.

Prognosis

Daily treatment with free biotin usually results in rapid improvement of the skin condition, hair regrowth, and a lessening or cessation of seizure activity. Many children whose development has been affected by biotinidase deficiency have shown some improvement after treatment. Hearing and vision losses are less reversible. Children who are diagnosed at birth through newborn screening programs rarely develop symptoms if they are started on biotin replacement therapy immediately.

Bipolar disorder

Definition

Bipolar disorder is a psychiatric disorder characterized by severe and unusual changes in energy level, mood, and interactions with others. The mood swings associated with bipolar disorder are unpredictable, ranging from mania to depression. Mania is characterized by elevated or irritable mood; depression is characterized by sadness and loss of interest. Bipolar disorder causes significant impairment in social, occupational, and general functioning.

Description

Bipolar disorder is characterized by extreme fluctuations in mood and energy levels, which alternate over long periods of time. These episodes, appearing in cycles

Composite image of 58 MRI brain scans of individuals diagnosed with bipolar disorder. (*Science Source*)

throughout life, are referred to as mania and depression. Between episodes, approximately two-thirds of bipolar patients are free of symptoms, with the remainder experiencing residual symptoms. A small percentage of patients experience chronic incessant symptoms despite treatment.

Bipolar disorder type I is the classic form of the illness involving recurrent cycles of extreme manic and depressive episodes. Type II bipolar disorder patients never develop severe mania. Rather, they experience milder episodes called hypomania that alternate with depression. A sub type called bipolar disorder mixed features is used to describe people who have symptoms of the disorder that do not clearly meet criteria for type I or type II. People with the mixed-features type often have hypomanic and depressive symptoms at the same time. A mild form of the disorder called cyclothymic disorder also involves symptoms that do not meet the criteria for types I or II, yet last for at least two years. A severe type, called rapid-cycling bipolar disorder, involves four or more episodes of illness within a 12-month period. Multiple episodes may occur within one week or day. Rapid cycling tends to occur later in the course of illness and is more common in women.

Manic episodes are commonly associated with irritability, decreased need for sleep, euphoria (an exaggerated perception of feeling good), social extroversion (excessive friendliness), and grandiosity (feeling more important than one truly is). Depressive episodes are commonly associated with fatigue, impaired concentration and

judgment, and altered sleep and appetite patterns. The depressive cycle can further progress to feelings of excessive shame and guilt, leading to suicidal thoughts. Bipolar disorder is a major affective disorder.

Genetic profile

There is no single gene or environmental factor that causes bipolar disorder. Like other mental illnesses, multiple factors together may contribute. Still, there is a strong tendency for bipolar disorder to run in families. The Child and Adolescent Bipolar Foundation (CABF) reports that the risk for a child of one bipolar parent to develop the disorder is 15% to 30%. If both parents have bipolar disorder, the risk for each child increases to 50% to 75%. The risk in siblings and fraternal twins is 15% to 25%. The risk in identical twins is approximately 70%. Research in identical twins indicates that genes and other factors play roles in developing bipolar disorder.

For the most part, studies show that certain genes can make a person more susceptible to a psychiatric disorder such as bipolar disorder. There appears to be a potential genetic correlation between bipolar disorder and mutations in specific regions of chromosomes 13, 18, and 21. The building blocks of genes, called nucleotides, are normally arranged in a specific order and quantity. If they are repeated in a redundant fashion, a genetic abnormality often results. Some evidence exists for a special type of nucleotide sequence (CAG/CTG repeats) in patients with type II bipolar disorder on chromosome 18. However, not all bipolar patients have this mutation, and the presence of this sequence does not worsen the disorder or change the age of onset.

Although as of 2021, no genes have been found that definitely cause bipolar disorder, many gene mutations have been identified that contribute to bipolar disorder. Among these candidate genes are: *G72/DAOA*, *DISC1*, and *NRG1*, which also have been associated with risk for schizophrenia. There are other candidate genes for bipolar disorder:

- *TPH2* also has been associated with major depressive disorder and major affective disorder 1.
- The *BDNF* gene encodes a protein related to nerve growth factors in the brain.
- The *5-HTT* gene encodes a protein involved in the transport of the neurotransmitter serotonin from synapses to presynaptic neurons.
- *DAT1* mediates reuptake of dopamine from the synapse and has been associated with bipolar disorder and ADHD.

In 2021, researchers at the National Institute of Mental Health (NIMH is one of the National Institutes of Health) explored how major mental disorders such as

bipolar disorder, schizophrenia, and major depressive disorder share common genetic traits but produce different symptoms and presentation in each affected individual. The researchers looked for answers in the brain's transcriptome, the transcripts of instructions for creating proteins to build and maintain cells. When they compared study subjects with mental disorders to those without mental disorders, they found differences in how the transcripts were expressed in subjects with and without different disorders. Parts of a gene's instructions may be included or omitted during the transcription process. The researchers found that a common genetic variant that regulates this inclusion and exclusion process, called splicing quantitative trait loci (sQTLs), may play a key role in the inherited risk for each disorder.

Demographics

According to the National Institutes of Mental Health (NIMH), approximately 2.8% of the United States adult population has bipolar disorder. It is estimated that more than 5 million adult Americans are affected. Type I is more common than type II. Approximately 25% to 50% of individuals with this type of disorder attempt suicide, with 11% actually committing suicide. Bipolar type I occurs equally in both sexes, but type II and rapid-cycling bipolar disorder are more common in women than in men. Women may also be at increased risk of developing subsequent episodes in the immediate time period after giving birth. In regard to race, bipolar disorder is thought to be under- or misdiagnosed in African Americans as of 2021. Bipolar disorder runs in families, with the rate of disease in identical twins being higher than that in fraternal twins. The age of onset varies greatly. The age range of onset may be in early childhood or up to 50 years of age, with a mean of 25 years. Some patients who have been previously diagnosed with recurrent major depression may have bipolar disorder yet not develop a manic episode until 50 years of age. However, for most patients, mania onset after 50 years of age is due to other medical disorders such as cerebrovascular disease.

Signs and symptoms

Bipolar disorder causes recurrent dramatic mood swings that range from manic highs to depressive lows. There are often periods of normal mood in between episodes of mania and depression. Severe changes in energy and behavior accompany the swings in mood.

Manic episode symptoms include:

- increased energy, activity, and restlessness
- excessively high, euphoric mood
- extreme irritability and reactivity
- racing thoughts and fast speech that jump from one topic to another (known as "flight of ideas")

3D MRI images of the brain of a person with bipolar disorder.
(Science Source)

- distractibility due to unimportant events and the inability to concentrate
- reduced perceived need for sleep
- unrealistic beliefs in one's abilities, powers, or importance
- poor judgment and impulsive behaviors
- increased sexual drive
- provocative, intrusive, or aggressive behavior
- denial that anything is wrong

Depressive episode symptoms include:

- persistent sad, anxious, or empty mood
- feelings of irritability, hopelessness, or negative mood
- feelings of guilt, worthlessness, or helplessness
- inability to take pleasure in activities
- fatigue
- inability to concentrate and poor judgment
- extreme sleep patterns
- extreme appetite changes that result in weight change
- chronic pain or physical discomfort in the absence of physical illness or injury
- thoughts of, and/or attempts at, suicide

Some people with type II bipolar disorder have depressive episodes concurrent with mood reactivity (mood improves with positive event) and can switch from depression to hypomania. Hypomania is characterized as a mild or moderate level of mania. Because hypomania is less severe, it may be associated with increased

KEY TERMS

Neuroprotective—Conveying some form of protection from injury to the nervous system.

Nucleotides—Building blocks of genes arranged in a specific order and quantity.

functioning and enhanced productivity. However, hypomania is not a normal state of mind. Without proper treatment, it may eventually progress into severe mania or switch into depression. Severe episodes of mania or depression may also include symptoms of psychosis. Psychotic symptoms include visual or auditory hallucinations and delusions. Psychotic symptoms in bipolar disorder tend to reflect the current extreme mood episode. During mania, psychotic delusions may include grandiosity, such as believing one has special powers of flight or extreme financial wealth. During depressive episodes, delusions may include paranoid fears of being poisoned or the belief that one has committed a terrible crime. Because of these psychotic symptoms, bipolar disorder is sometimes mistaken for schizophrenia.

Some people who have bipolar disorder have a mixed state of symptoms. A mixed bipolar state is characterized by symptoms of agitation, sleeplessness, appetite changes, psychosis, and suicidal tendencies. A depressed and hopeless mood may occur in conjunction with extreme energy. Signs of bipolar disorder may also be demonstrated outside of mental illness symptoms in behaviors such as alcohol or drug abuse, poor work performance, strained interpersonal relationships, or sexual promiscuity. Symptoms of bipolar disorder with postpartum onset usually occur within four weeks after childbirth. Bipolar disorder with a seasonal pattern displays symptoms related to seasonal change and latitude. The prevalence of the season-specific bipolar symptoms increases with higher latitudes and winter months.

Children and young adolescents who have bipolar disorder tend to have episodes that are less clearly defined than adults with the disorder. Young people often experience very fast swings (rapid cycle) between mania and depression within the same day. Children in a manic episode are more likely to be irritable and destructive than elated. Children and young adolescents are also more prone to mixed symptoms. Bipolar disorder in children and adolescents can be difficult to distinguish from other problems associated with this age group. Symptoms of irritability and aggressiveness may indicate bipolar disorder or may be symptoms of attention-deficit/hyperactivity

disorder, conduct disorder, oppositional defiant disorder, other types of mental disorders, or drug abuse.

Diagnosis

Bipolar disorder is often difficult to diagnose. As with other mental illnesses, it cannot yet be identified through simple laboratory tests. A diagnosis of bipolar disorder is made on the basis of symptoms, course of illness, and family history. The diagnostic criteria for bipolar disorder are described in the *Diagnostic and Statistical Manual for Mental Disorders*, fifth edition (DSM-5). A manic or hypomanic episode is diagnosed when elevated mood or energy, including three or more associated symptoms, lasts for one week or longer. A depressive episode is diagnosed when five or more of the associated symptoms last two weeks or longer. For mixed-features bipolar disorder, the criteria must be met for manic and depressive episodes at the same time. A mental status examination during an episode reveals obvious symptoms associated with bipolar disorder.

Bipolar disorder should be distinguished from major depressive disorder. Close friends, family members, and roommates are often very helpful in assisting the clinician to make the correct diagnosis. Individuals who exhibit bipolar disorder depressive episodes often present with signs of eating more (hyperphagia), sleeping more (hypersomnia), having very low energy levels, being overweight, and experiencing deteriorating mood during evening hours. The person with bipolar disorder also tends to deny or minimize obvious signs of illness. Contrarily, people with major depression usually have anxiety, sleeping difficulty, loss of appetite, and loss of weight. They tend to feel worse during morning hours but improve as the day progresses.

Suicide is the major complication of bipolar disorder, and its occurrence is related to the duration of the depressive episode. The longer the depressive episode lasts, the higher the risk of suicide. Alcoholics and patients with other chronic medical diseases are particularly prone to planning and implementing suicide attempts.

The four main groups who are likely to carry out a suicide attempt include the following:

- Individuals who are overwhelmed by life problems. Suicide attempts in this group tend to be related to aggression and impulsive behaviors, not significant depressive episodes.
- Individuals who are attempting to control others.
- Individuals who are chronically ill with another medical condition or disease.
- Individuals with other severe types of mental illness such as psychosis, delusions, or paranoia.

Treatment and management

Most individuals with bipolar disorder can achieve substantial stabilization of mood swings and related symptoms with proper treatment. Treatment of bipolar disorder is achieved through medication and psychosocial interventions. Medications for bipolar disorder are prescribed by psychiatrists, physicians with advanced training and expertise in the diagnosis and treatment of mental disorders. Primary care physicians may also prescribe medications used to treat bipolar disorder, but it is recommended that bipolar patients see a psychiatrist for treatment.

Medications

Mood-stabilizing medications may be used for long-term maintenance and preventive treatment of bipolar disorder episodes. In the acute phase, the choice of medication for bipolar disorder depends on the stage or type of current episode. The drugs used to treat an acute manic episode are primarily the antipsychotics and benzodiazepines (lorazepam, clonazepam). In the presence of psychotic symptoms, atypical antipsychotics may be used to treat the psychotic symptoms and acute mania. For depressive episodes, antidepressants may be used. These may be added temporarily to treat episodes of mania or depression that break through despite mood stabilizer treatment.

Mood stabilizers have an effect that decreases the extremes of manic and depressive episodes. Lithium was the first mood stabilizer approved by the Food and Drug Administration (FDA) for the treatment of mania and the prevention of both manic and depressive episodes. Lithium carbonate is a first-line medication used in the long-term preventive treatment of extreme mood episodes in bipolar disorder. Lithium carbonate is considered to play a neuroprotective role in brain function. The beneficial effects of lithium carbonate usually appear one or two weeks after administration of oral doses. Lithium treatment has a high response rate, with 70% to 80% of patients with acute manic attacks showing an improvement of symptoms. However, it has many side effects, including gastrointestinal discomfort, diarrhea, baldness, skin eruptions, and fluid retention. Lithium is primarily useful as a prophylactic (preventive) medication for future attacks.

Multiple anticonvulsant medications, such as valproate (Depakote), carbamazepine (Tegretol), and lamotrigine (Lamictal) also act as mood stabilizers. However, not all anticonvulsant medications have been FDA-approved for this use. Valproic acid is a second-line medication intended for patients who respond poorly to lithium or cannot tolerate the side effects. Valproic acid has

QUESTIONS TO ASK YOUR DOCTOR

- What is the basis of your diagnosis of bipolar disorder for my child?
- Are there other conditions with which this disorder may be confused?
- How do you know it is not one of the other similar conditions?
- What medications are available for the treatment of bipolar disorder?
- What side effects should we expect with each medication?
- Do you recommend psychological counseling along with medication in treatment of our child's bipolar disorder?

proven effective in treating and preventing mania, but is especially useful in treating rapid-cycling bipolar disorder. It can be used alone or in combination with lithium. For treatment of depressive bipolar episodes, mood stabilizers are preferred over antidepressants, because antidepressants may cause a switch into a manic episode or aggravate irritability in mixed-symptom mania. Gabapentin (Neurontin) is not a mood stabilizer, but it may have antidepressant and anti-anxiety effects.

Psychosocial interventions

Cognitive-behavioral therapy helps people who have bipolar disorder learn how to change thoughts and patterns that are harmful into more positive thoughts and behaviors. Psychosocial interventions also include patient education and family-focused therapy. It is important for patients to receive social support and illness-management skills. Family and friends must be aware of the high rates of social dysfunction and marital discord. Involvement in national support groups (e.g., the National Depressive and Manic-Depressive Association) may be helpful.

Psychoeducation usually focuses on all of the following:

- assessing which parameters will have an impact on the outcome of the patient's disease
- communicating the boundaries and requirements of treatment
- undergoing a personal cost-benefit analysis concerning specific treatment directions
- implementing a follow-up program

- implementing future directions that may include adjustment or change interventions

Genetic counseling should be included in family education programs, since the predisposition for this disorder has been recognized to increase among first-degree relatives.

Prognosis

Although the episodes of mania and depression appear in cycles, bipolar disorder is a long-term illness that currently has no cure. The long-term prognosis for bipolar disorder is variable. It is critical that bipolar patients maintain consistent and strict adherence with prescribed medications. Patients taking psychotropic medications must understand the importance of regular dosing as prescribed and the necessity of frequent psychiatric follow-up visits. In comparison to major depression (unipolar), bipolar disorder is usually associated with longer depression, more severe depressive symptoms, more relapses, more incapacitation, and more hospitalization. Some studies have shown that early-onset bipolar disorder is associated with more recurrences but not necessarily worse outcomes. Psychotherapy and education can improve prognosis by providing patients and family members with pertinent information about relapses, non-compliance with prescription medications, and specific adjustments necessary for the welfare of the affected individual.

Many individuals with bipolar disorder can lead productive lives when the illness is effectively treated. However, without treatment, the prognosis is very poor. The natural course of bipolar disorder tends to worsen over time, with increased frequency and severity of the manic and the depressive episodes. In most cases, proper treatment can reduce the frequency and severity of episodes to maintain a good quality of life. Remaining on medications, even during well times, is essential for keeping the disease under control and reducing the risk of recurrent worsening episodes.

Birt-Hogg-Dubé syndrome

Definition

Birt-Hogg-Dubé syndrome is a rare genetic disorder characterized by numerous skin tumors, lung cysts, pneumothorax, and kidney tumors. It is an autosomal recessive disorder.

Description

Birt-Hogg-Dubé syndrome (BHD) was first described in 1977 by three Canadian researchers who found small papular lesions on the face and neck of 15 of 70 individuals involved in an ongoing research study. The researchers

KEY TERMS

Autosomal dominant—A genetic trait that is expressed when only a single copy of a gene is present.

Dermabrasion—Scraping or sanding the epidermal layer of the skin to remove scars and other marks or wrinkles.

Electrodessication and curettage—A procedure by which a papula is cut out of the skin (curettage) and bleeding controlled with an electric current (electrodessication).

Fibrofolliculomas—Small white or yellow dome-shaped benign growths on hair follicles.

Laser ablation—Removal of a skin papula with a laser beam.

Nephrectomy—Surgical removal of a kidney.

Papula—A small raised area of the skin that lacks visible fluid.

Pneumothorax—Abnormal accumulation of air in the chest cavity outside the lung, often responsible for a collapsed lung.

Prevalence—The number of individuals living with a particular illness within a particular population at any given time. Prevalence is often expressed in terms of number of individuals per 100 or per 1,000 members of the population.

Renal—Related to the kidneys.

Sign—An indication of disease, injury, or other physical problem that can be observed by someone other than the person experiencing these conditions.

Symptom—An indication of disease, injury, or other physical problem reported by the person experiencing these conditions, but not by some outside observer.

found what appeared to be three types of lesions: fibrofolliculomas, trichodiscomas, and acrochordons, the most common of which were fibrofolliculomas—small white or yellow dome-shaped benign growths on hair follicles, which is the only skin finding specific for Birt-Hogg-Dubé syndrome. The lesions are generally found on the head, neck, face, and upper chest. They tend to appear first during a person's 20s or 30s. Over time, they become larger and more numerous.

The initial description of BHD was based on skin findings. Therefore, historically, most people with BHD were identified as a result of their skin findings. However,

individuals have been diagnosed with BHD who have pulmonary involvement and/or renal tumors without the associated skin findings. Almost 90% of individuals with BHD have multiple and bilateral lung cysts and about 25% have had at least one pneumothorax. Similar to lung cysts, there are usually multiple, bilateral renal tumors. The average age at which tumors are first detected in affected BHD patients is 48. Severity of the condition differs significantly among members of a family in which the condition occurs.

Demographics

The prevalence of the disorder is estimated at about 1 in 200,000 individuals and is estimated to be underdiagnosed due to its variable presentation. No racial or gender differences in its occurrence have been discovered.

Signs and symptoms

Birt-Hogg-Dubé syndrome is caused by one or more mutations in the *FLCN* (folliculin) gene, found on chromosome 17. The gene directs the synthesis of the protein called folliculin. This protein's precise function has not been determined, but researchers believe it may be a tumor suppressor; tumor suppressors help control the growth and division of cells.

Classic symptoms of BHD are the appearance of multiple bilateral lung cysts and distinctive papulae on the head, face, neck, and upper chest. Up to 34% of individuals with BHD develop kidney tumors. The most common renal tumors are hybrid oncocytic renal cell carcinoma, oncocytoma, chromophobe renal cell carcinoma, and clear cell renal cell carcinoma. Other manifestations include a tendency to have spontaneous pneumothorax, oral papules, parotid oncocytomas, and possibly thyroid and colon cancer.

Diagnosis

CAT scans are used to detect the presence of cysts in the lungs and renal tumors. Genetic testing for mutations in the *FLCN* gene is indicated when there are at least five distinctive papulae characteristic of the syndrome.

The five characteristics include:

- histological confirmation that at least one papula is a fibrofolliculoma
- facial papules histologically confirmed to be angiofibroma when the patient does not have tuberous sclerosis complex or multiple endocrine neoplasia type 1
- multiple and bilateral renal tumors of specific pathology
- a single renal tumor of associated pathology and a family history of renal tumors

QUESTIONS TO ASK YOUR DOCTOR

- How do you assess the severity of a case of Birt-Hogg-Dubé syndrome?
 - What treatments are available for the type of BHD that I have?
 - What tests can you perform to determine the effects of BHD on internal organs?
 - What are the undesirable side effects of cosmetic treatments for the papulae associated with BHD?
 - Has there been any breakthrough in research on possible treatments for BHD?
- a family history of primary spontaneous pneumothorax without a history of smoking or COPD.

Treatment and management

There is no definitive medical treatment for the dermatological manifestations of BHD. A number of standard procedures, such as surgical removal of fibrofolliculomas, laser ablation, dermabrasion, electrodestruction and curettage are temporarily successful. However, lesions tend to recur. Of significantly greater concern is the possibility of lung cysts and tumors. Whenever possible, surgical removal of individual cysts and tumors is preferred. Still, in more serious cases, complete nephrectomy may be necessary. Pneumothorax is treated by standard procedures used for the problem, involving removal of air in the chest cavity in order to allow a lung to reinflate.

Prevention

There is no way to prevent contracting BHD, but some steps can be taken to reduce the severity and most serious consequences of the disorder. For example, patients should not smoke, since smoking is a risk factor for diseases of the lungs and kidneys. Additionally, a person with BHD should avoid situations in which he or she is exposed to unusually high atmospheric pressures, since they can increase the probability of pneumothorax.

Prognosis

Visible manifestations of BHD are cosmetically undesirable, but not life-threatening. The greatest long-term health issues are related to cysts and tumors associated with the lungs and kidney. Prognosis for these problems depends on their severity and the rate at which they develop.

Bloom syndrome

Definition

Bloom syndrome is a rare inherited genetic disorder characterized by short stature, a predisposition to cancer, a compromised immune system, and other medical problems. It is caused by changes (mutations) in the *BLM* gene that is involved in copying and repairing DNA. These changes cause chromosome instability and breakage. Bloom syndrome is also known as congenital telangiectatic erythema.

Bloom syndrome: pedigree analysis chart (Gale)

Description

Bloom syndrome was first described by Dr. David Bloom in 1954, in patients with short stature (dwarfism) and telangiectatic erythema (red dilated superficial capillaries on the face). These signs, along with sun sensitivity and immune-system deficiency, are the distinguishing characteristics of Bloom syndrome. Genomic instability, which is manifested by the excessive exchange of genetic material between chromosomes, results in a very high incidence of cancer. Immunodeficiency also predisposes Bloom syndrome patients to cancer, as well as to various infections.

DNA is the molecule that encodes the genetic information and determines the structure, function, and behavior of cells. The *BLM* gene, whose official name is “Bloom syndrome, RecQ helicase-like,” produces the BLM protein. This protein is a member of the RecQ helicase family of proteins that bind to DNA and temporarily unwind double-stranded DNA. This creates single-stranded DNA templates for replication (copying) before cell division with the purpose of repairing damaged DNA and transcribing DNA into RNA to produce protein. The BLM protein also may function in a post-replication recombination process that resolves errors generated during replication. In preparation for cell division, the DNA of each chromosome is copied (replicated) to form two identical sister chromatids. Small sections of DNA can be exchanged at this time, in a process called sister-chromatid exchange (SCE). BLM normally helps prevent SCE in order to maintain genome stability during replication. BLM also may help restart the process of replication when it stalls.

Mutations (changes) in the DNA sequence of the *BLM* gene prevent it from making BLM protein. Without normal BLM protein, DNA replication restarts through SCE, which decreases chromosome stability. In Bloom syndrome, the frequency of SCE is increased about 10-fold. As a result,

the chromosomes of people with Bloom syndrome accumulate gaps, breaks, and structural rearrangements. These interfere with normal cell functioning, leading to the medical problems characteristic of Bloom syndrome. These chromosomal problems also greatly increase the risk of cancer. Furthermore, copying mistakes or damage to DNA are less likely to be repaired, leading to additional mutations. The absence of normal BLM protein may also increase the rate of cellular death, accounting for the slow growth observed in people with Bloom syndrome.

Genetic profile

Bloom syndrome is inherited in an autosomal recessive manner. “Autosomal” means that the *BLM* gene is not located in the X or Y sex chromosomes, so it is inherited equally by males and females. “Recessive” means that Bloom syndrome only develops in the presence of two defective *BLM* genes, one inherited from the mother and one from the father. The parents are carriers of the affected gene, but typically do not have symptoms of Bloom syndrome. However, parents with a single defective *BLM* gene have a 50% risk of passing that gene on to each of their offspring. If both parents carry the defective gene, each of their children has a 25% chance of having the disorder. The *BLM* gene is located on the long (q) arm of chromosome 15, within band 26.1 (15q26.1).

More than 70 different mutations that cause Bloom syndrome have been identified in *BLM* genes. Almost all cases of Bloom syndrome among people of Ashkenazi (Central and Eastern European) Jewish ancestry have the mutation *blmAsh*. This mutation replaces six DNA nucleotides (building blocks) with seven different nucleotides at position 2281 in the gene. *blmAsh* is referred to as 2281delta6ins7, where “delta” means deletion and “ins” means insertion. This mutation causes a short, nonfunctional BLM protein. Various other known *BLM* gene

KEY TERMS

Autosomal recessive—A gene, such as the Bloom syndrome gene, that is located on a chromosome other than the X or Y sex chromosomes and encodes a protein that is not expressed unless the second copy of the same gene inherited from the other parent is also mutated or recessive.

BLM—The gene and protein that when mutated cause Bloom syndrome.

blmAsh—The mutation in the BLM gene, known as 2281delta6ins7, that causes Bloom syndrome in people of Ashkenazi Jewish ancestry.

Carcinoma—Any cancer that arises in the epithelium, the tissue that lines the external and internal organs of the body.

Carrier—Having one abnormal gene for a trait, such as Bloom syndrome, and one normal gene for the trait (a heterozygote), without signs or symptoms of the disorder but the possibility of passing the abnormal gene on to offspring.

Chromatid—Each of the two strands formed by replication (copying) of a chromosome; chromatids are held together by the centromere, which subsequently divides and separates the two chromatids to form two new chromosomes.

Fecal blood testing—Examination of the stool for evidence of blood, which may be a sign of a digestive-tract cancer.

Helicase—An enzyme, such as BLM, that unwinds and separates DNA during replication (chromosome copying prior to cell division).

Leukemia—Cancer caused by overproduction of white blood cells.

Lymphoma—A malignant tumor of the lymphatic tissue.

Sigmoidoscopy—Visual examination of the inside of the rectum and sigmoid colon, using a lighted, flexible tube connected to an eyepiece or video screen for viewing.

Sister-chromatid exchange (SCE)—Exchange of DNA between sister chromatids during DNA replication; excessive SCE can cause the gaps, breaks, and structural rearrangements of chromosomes that are diagnostic of Bloom syndrome.

Telangiectatic erythema—A localized collection of dilated blood capillaries near the surface of the skin; congenital telangiectatic erythema is another name for Bloom syndrome.

mutations change a single amino acid in the protein or produce no BLM protein.

Demographics

Bloom syndrome is very rare, affecting fewer than one in six million people in the general population. However, in the Ashkenazi Jewish population, approximately 1 in 50,000 are affected with Bloom syndrome, with approximately 1 in 100 people carrying a *BLM* gene mutation. These carriers do not appear to have an increased risk for cancer or other symptoms associated with Bloom syndrome. Furthermore, carriers have normal or near-normal genome stability. About one-third of all people with Bloom syndrome are of Ashkenazi Jewish ancestry. However, worldwide, Bloom syndrome may be underdiagnosed or mistaken for another rare disorder.

Signs and symptoms

Almost all people with Bloom syndrome are very sensitive to sunlight and are of small stature. Newborns are generally of low birth weight. The average height for adult males is 58.1 in. (147.5 cm) and for females is 54.6 in. (138.6 cm). The head and brain are often small. The head may be dolichocephalic—relatively long and narrow. Infants and children have very little body fat and remain thin as adults.

Both benign (noncancerous) and malignant (cancerous) tumors arise at an early age and with great frequency in a variety of cell types and locations. Malignant tumors affect 37% of patients between ages 2 and 46, with a mean age of cancer diagnosis of 24 years. Lymphomas and leukemias are common, usually before age 25. Carcinomas are common as well, usually developing after age 20, most often in the colon, skin, breast, or cervix. Many people develop more than one type of cancer. Radiation treatments and chemotherapy for cancer may lead to further complications because these treatments can further damage fragile chromosomes.

Other common signs and symptoms that vary in severity may include:

- unique facial features like a prominent nose, small lower jaw, and protuberant ears, in addition to a long, narrow face
- a high-pitched, squeaky voice
- repeated respiratory tract and ear infections in infants
- vomiting and diarrhea in infants, possibly leading to a life-threatening loss of body water (dehydration)
- telangiectatic erythema—a reddish “butterfly” rash on the cheeks and nose upon exposure to sunlight; it can vary from a faint blush in the summer to severely

disfiguring, flaming-red lesions and dilated blood vessels

- similar rashes on other parts of the body exposed to sunlight, especially the arms and hands
- patchy skin pigmentation developing during childhood, with some spots of less pigment (hypopigmentation) and some with excessive pigment (hyperpigmentation)
- infertility in most males due to abnormally small testes and the inability to produce sperm
- reduced fertility and early menopause in women
- early-onset type 2 diabetes (at an average age of 25 years)
- increased susceptibility to bacterial infections due to immune-system deficiency
- chronic obstructive pulmonary disease (COPD)
- occasionally, minimal-to-severe intellectual disabilities
- learning disabilities and/or short attention span in individuals with normal intelligence
- a persistent optimistic attitude

Diagnosis

Bloom syndrome may be suspected at birth but is generally confirmed by cytogenetic SCE analysis of the chromosomes from a blood sample. Bloom syndrome is the only known disorder that causes congenital (present at birth) SCE. Analysis for SCE may be performed for any patient with unexplained growth deficiency regardless of whether or not other signs of Bloom syndrome are present. In addition to an approximately 10-fold increase in SCE, unique chromosome structures called quadriradials are usually visible. Although SCE and quadriradials are present in cells from individuals without Bloom syndrome, they occur much less frequently.

Genetic testing can determine the specific BLM mutation. Genetic testing is also used to identify Ashkenazi Jewish carriers of a BLM mutation with an accuracy of up to 99%. In February 2015, the Food and Drug Administration (FDA) ruled that the personal genomics testing company, 23andMe, could market a genetic test for BLM mutations. This was the first disease-predicting genetic test allowed by the FDA after it halted all of 23andMe's health-prediction services in 2013. Genetic counseling and testing is recommended before conception, and prenatal diagnosis is available for couples with previously identified BLM mutations.

Treatment and management

There is no treatment or cure for Bloom syndrome. However, early diagnosis and management can relieve some symptoms and increase life expectancy. For example, babies and young children with Bloom syndrome are often poor eaters, avoiding nutritious food and

QUESTIONS TO ASK YOUR DOCTOR

- Should my partner and I have genetic testing for Bloom syndrome before conceiving a child?
- What information will genetic testing provide?
- Is prenatal testing available for Bloom syndrome?
- What characteristic signs and symptoms are associated with Bloom syndrome?
- What treatments are available for controlling the progression of Bloom syndrome?
- What is the normal life expectancy of a child with Bloom syndrome?

multivitamins that may improve growth. Treatment with growth hormone has generally been ineffective and may further increase cancer risk. Skin lesions can be controlled by avoiding sunlight, wearing a hat, and using sunscreen. Avoidance of sun exposure is especially critical in the first few years of life, since the severity of skin lesions appears to depend on early exposure. Immune-system deficiencies require that infections be treated promptly.

Cancer surveillance is of utmost importance. After the age of 20, annual sigmoidoscopy and fecal blood testing are recommended for colon cancer, as well as Pap smears and mammography for cervical and breast cancers, respectively. Patients should be followed closely by a physician or clinic specializing in Bloom syndrome to detect subtle symptoms of carcinomas. Early surgical removal of tumors provides the best chance for a cure. Removal and storage of bone marrow early in life is sometimes recommended so that the patient's own bone marrow is available for later cancer treatment. Patients should avoid x-rays, chemotherapy drugs, and environmental exposures that may damage their fragile chromosomes.

Prognosis

The mean life expectancy of people with Bloom syndrome is 23 years and the average life expectancy is 27 years. There are no reports of patients surviving past 48 years. About 80% of deaths are caused by cancer. Chronic respiratory infection is the second most common cause of death.

Blue rubber bleb nevus syndrome

Definition

Blue rubber bleb nevus syndrome (BRBNS) is a rare disorder characterized by hemangiomas of the skin and gastrointestinal (GI) tract. Hemangiomas are benign or noncancerous tumors of newly formed blood vessels and skin. This syndrome derives its name from these distinctive rubber-like skin lesions, or blebs. Blebs are nevi (skin anomalies, such as moles) that measure more than 5 millimeters around.

Description

In 1860, G. G. Gascoven first reported the association of cutaneous or skin nevi and intestinal lesions with GI bleeding. William Bean in 1958 first used the term *BRBNS* to describe the rubber-like tumors. Because of his description, BRBNS is sometimes called Bean syndrome. Besides the skin and GI tract, nevi are found on

KEY TERMS

Anemia—A blood condition in which the level of hemoglobin or the number of red blood cells falls below normal values. Common symptoms include paleness, fatigue, and shortness of breath.

Cutaneous—Of, pertaining to, or affecting the skin.

Endoscopy—A slender, tubular optical instrument used as a viewing system for examining an inner part of the body and, with an attached instrument, for biopsy or surgery.

Nevus (plural, nevi)—Any anomaly of the skin present at birth, including moles and various types of birthmarks.

all internal organs and even the brain. Nevi are birthmarks of the skin that are probably hereditary because they are not caused by external factors.

Genetic profile

Mutations in the *TEK* gene on the short arm of chromosome 9 were identified as the cause of BRBNS in 2016. Some cases of BRBNS are familial and support an autosomal dominant form of inheritance, meaning that only one copy of the nonworking gene is required to manifest the condition. An affected parent has a 50% chance of passing the disorder to his or her offspring. However, most cases are sporadic without a familial tendency.

Demographics

Fewer than 180 cases have been reported worldwide. BRBNS affects all races and both sexes and may be present at birth. The effects on life expectancy are unknown because so few cases exist.

Signs and symptoms

The distinctive blue skin blebs are the hallmark of BRBNS and are not cancerous. Composed of skin and large dilated blood vessels, the nevi do not disappear and are found on internal organs such as the stomach, liver, spleen, heart, bone, muscle, bladder, and vulva. They are easily compressible and refill after compression. Occasionally, the nevi are painful. Ranging in size from millimeters to several centimeters, the nevi can number from a few to hundreds. As the patient ages, they can increase in size and number. In rare cases, large lesions can cause skeletal deformities that may lead to amputation.

Nevi are usually present at birth. Sometimes, however, they may not appear until age two or three.

Patients with BRBNS develop an extreme paleness or pallor of the skin. This paleness results because anemia, a low blood count, decreases the amount of oxygen available to the surface skin. Often patients complain of fatigue that results from low iron stores and the anemia.

Chronic or acute bleeding in the GI tract may be detected when blood is present in the stool. Chronic bleeding causes anemia, pallor, fatigue, and low iron stores. Iron supplements will help to increase the blood count. Acute bleeding in the GI tract happens quickly and can rapidly decrease a normal blood count. Immediate blood transfusion or surgery to remove the bleeding nevus can correct this condition.

Diagnosis

The first key to diagnosis of this condition is the appearance of the skin nevi. If they do not have the distinct rubbery texture and blue color and do not refill after they have been compressed, another diagnosis should be considered. Endoscopy is required to examine the GI tract for nevi. If they are present, then the diagnosis is confirmed. However, lack of nevi in the GI tract does not completely rule out BRBNS, since nevi may not develop until adolescence.

During an endoscopy, a viewing instrument attached to a flexible tube is passed through the mouth to the small intestine. The tube can also be inserted through the rectum to the colon. The doctor can then examine the GI tract for nevi.

A patient will require blood tests to assess anemia and iron deficiency as well as a stool test for the presence of blood. Although nevi may be found on the brain, few patients have neurological signs such as seizures or partial paralysis.

Treatment and management

Treatment of BRBNS will depend upon the severity, number, size, and location of the nevi. Skin lesions that are life-threatening can be safely removed by surgery or laser therapy. The severity of bleeding from GI lesions will determine how they are treated. Surgery can remove single lesions; however, the number may be too great to excise them all. Treatment methods that are less invasive than surgery use endoscopy to tie off bleeding nevi.

Patients who have neurological signs should have magnetic resonance imaging (MRI) of the brain to discover the extent of nevi. Seizures can usually be controlled by medications. Physical therapy may improve paralysis.

QUESTIONS TO ASK YOUR DOCTOR

- How did this disorder get its name and what does the name mean?
- Are there signs and symptoms of blue rubber bleb nevus syndrome that clearly distinguish the disorder from other medical conditions?
- What treatments would my child require if he or she were to be born with blue rubber bleb nevus syndrome?
- Can you predict the life expectancy of a child born with this disorder?

Prognosis

Although BRBNS is a chronic progressive disease, it does not appear to be fatal; most patients can expect to have a normal lifespan. If the GI bleeding and anemia are treated, the patient will usually cope well. If a patient expresses concerns about his or her physical appearance, psychological counseling should be considered.

Brachydactyly

Definition

Brachydactyly (BD) refers to shortening of the fingers or toes due to underdevelopment of the bones in the hands or feet.

Description

The word brachydactyly comes from the Greek terms “brachy,” meaning “short,” and “daktylos,” meaning “digit.” This term is used to describe the hands and feet of people who have shortened digits (fingers or toes). The digits themselves may be shorter than normal, or they may appear small because of shortening of the other bones in the hands or feet. This shortening occurs when one or more of the hand or foot bones fail to develop or grow normally.

BD is usually isolated, meaning that it is not associated with any other medical problems. BD may occur along with other physical differences or health problems, often as part of a syndrome.

BD occurs in a variety of patterns, depending upon which hand or foot bones are affected and how severely they are shortened. It is important to know some basic information about the bone structure of the hands and feet in order to understand the various patterns of BD. Beyond the wrist and ankle, each hand and foot contains 19 tube-shaped (tubular) bones in a specific arrangement. For purposes of orientation, the fingers and toes are numbered from one (thumb or great toe) to five (little finger or little toe). When a fist is made, the bones in the hand that extend from the wrist to the knuckles are called metacarpals. There are five metacarpals, one for the thumb (first metacarpal) and each finger. Each thumb and finger contains several bones called phalanges. A single one of these bones is called a phalanx. The phalanges are arranged end to end and are separated by joints. The thumb has two phalanges, and each finger has three phalanges. The phalanges within a particular finger are named according to their location. The phalanges closest to the metacarpals are called the “proximal” phalanges, those in the middle of the fingers are called the “middle” phalanges, and those at the ends of the fingers are called the “distal” or “terminal” phalanges. The thumbs have only proximal and distal phalanges.

The foot bones are very similar to the hand bones. Like the metacarpals, there are five metatarsal bones that extend from the ankle to each of the toes. The bones in the toes are also called phalanges. There are two phalanges in the great toe and three phalanges in each of the other toes.

KEY TERMS

Clinodactyly—An abnormal inward curving of the fingers or toes.

Digit—A finger or toe.

Metacarpal—A hand bone extending from the wrist to a finger or thumb.

Metatarsal—A foot bone extending from the ankle to a toe.

Phalanges (singular, phalanx)—Long bones of the fingers and toes, divided by cartilage around the knuckles.

Symphalangism—Fusion of phalanges at their ends.

Syndactyly—Webbing or fusion between the fingers or toes.

BD can involve any of the phalanges, metacarpals, and metatarsals in many different combinations. The shortening of these bones may range from mild to severe. Sometimes certain bones are completely absent. Shortening of the bones may occur in one, several, or all of the digits. For a particular finger or toe, the entire digit may be short or only a particular phalanx may be underdeveloped. When BD involves the distal phalanges, the fingernails or toenails may be small or absent. A digit may also be of normal length but appear short due to shortening of its corresponding metacarpal or metatarsal bone. Reduced length of a metacarpal bone is often easiest to appreciate when the hand is held in a fist.

BD can also occur with other abnormalities of the hands and feet. When a phalanx is abnormally shaped, the finger or toe may be bent to one side (clinodactyly). Sometimes the digits have webbing between them (syndactyly). The phalanges may also be fused together at their ends (sympchalangism). This makes it difficult to bend a digit at the joint where the phalanges are fused.

BD frequently occurs in characteristic patterns that can be inherited through families. These patterns are classified as particular types of BD, depending upon which bones and which digits of the hands and/or feet are shortened. There are several classification systems used to describe these different types of BD. The system that is used most frequently was developed by Dr. Julia Bell in 1951 and is called the Bell Classification.

There are five main types of BD in the Bell Classification, which are designated A through E. Their major features are as follows:

- In type A, the middle phalanges of one, several, or all of the fingers and/or toes are shortened. This form of BD is

further divided into types A1, A2, and A3. In type A1, the middle phalanges of all digits and the proximal phalanges of the thumbs and great toes are shortened. People with this form of BD generally have hands and feet that appear small with relatively equal shortening of all digits. In type A2, the middle phalanges of the index finger and second toe are shortened and often abnormally shaped. In type A3, the middle phalanx of the fifth finger is shortened and this finger often bends toward the fourth finger. Several other forms of BD type A have also been described.

- In type B, the distal phalanges and nails of the fingers and/or toes are small or absent. The middle phalanges may also be shortened, and the tips of the thumbs and/or great toes may be broad or have a “duplicated” (double) appearance. In this type of BD, the digits typically look as though their tips have been amputated.
- In type C, the middle phalanges of all of the fingers may be shortened, but the fourth finger is least affected and is often the longest finger. The index and middle fingers may be bent toward the fourth finger. The first metacarpal bone can also be short, making the thumb appear small.
- In type D, the distal phalanges of the thumbs and/or great toes are shortened and broad.
- In type E, the metacarpals and/or metatarsals are shortened. The fourth and fifth metacarpals and metatarsals are most commonly shortened, but any of them may be affected.

Genetic profile

Many different genetic signals are required for normal formation of the hand and foot bones. BD is usually caused by abnormalities in these genetic blueprints. Sometimes BD can be caused by exposure to drugs or medications taken during pregnancy. Problems with blood flow to the hands or feet during fetal life may also cause BD.

The types of BD in the Bell Classification are inherited in families from one generation to the next. Their pattern of inheritance is autosomal dominant. This means that they are caused by abnormalities in only one copy of a gene from a particular gene pair. In fact, one form of BD (type A1) was the first human condition that was recognized to have this type of inheritance pattern. Autosomal dominant forms of BD can be inherited by a child of either sex from a parent of either sex. The gene change causing BD may also occur in a particular person for the very first time within a family. Each child born to a person having autosomal dominant BD has a 50% chance of also having BD. However, the degree of hand or foot abnormalities can be very different between people with

QUESTIONS TO ASK YOUR DOCTOR

- How likely is it that my child’s brachydactyly is a symptom of some other disease?
- Will it be necessary to have surgery or some other kind of treatment for my child’s condition?
- How will my child’s brachydactyly affect his or her probable lifespan?
- Should my child have counseling in order to deal more successfully with this medical condition?

the same type of BD, and even among members of the same family.

Until recently, nothing was known about the genes that cause BD. This has changed with the identification of the genes that cause two forms of autosomal dominant BD (types B and C) in the past several years. The gene causing BD type C was the first to be identified in 1997. The name of this gene is the “Cartilage Derived Morphogenetic Protein 1” gene, abbreviated as *CDMP1*. This gene is located on the long arm of chromosome 20 (at location 20q11.2) and provides an important genetic signal to the developing bones of the limbs. Most people with BD type C have abnormalities in one of their two copies of this gene.

The gene causing BD type B was identified in 2000. This gene is called *ROR2* and is located on the long arm of chromosome 9. Like *CDMP1*, *ROR2* also provides an important genetic blueprint for the normal development of bones. BD type B is caused by alterations in one copy of this gene.

One interesting feature of the *CDMP1* and *ROR2* genes is that they can also cause other medical conditions with bone problems that are much more severe than BD. This happens when both copies of either gene are altered in the same person. Another gene associated with autosomal dominant BD is the *HOXD13* gene on chromosome 2, linked to BD types D and E.

Demographics

BD occurs in people of many different racial and ethnic backgrounds. It is difficult to determine the overall frequency of BD in the general population because many people who have BD never seek medical attention for their shortened digits. Types A3 and D are the most common forms of BD, but their frequencies vary widely between groups of people from different backgrounds. For example, type A3 has been found in less than 1% of

Americans, compared to 21% of Japanese people. Because isolated forms of BD are generally inherited as autosomal dominant traits, they should affect males and females in equal numbers. However, several types of BD may be more common in females.

Signs and symptoms

BD is often evident at birth, but it may also develop or become more obvious during childhood. It usually does not cause pain or other physical symptoms. In fact, many people who have BD consider it to be a normal family trait rather than a medical condition. When BD does cause problems, they are usually related to the size, appearance, or function of the hands or feet. The altered appearance of the hands or feet may make persons with BD feel self-conscious. Shortening of the digits may also make it difficult to find comfortable shoes or gloves. In its severe forms, BD may affect a person's ability to grip objects or participate in certain jobs or leisure activities. Hand function may be especially affected when BD is associated with clinodactyly, syndactyly, or symphalangism. When BD is associated with significant deformities of the feet, walking may be difficult or painful.

In some cases, BD occurs in combination with other physical changes or medical problems. For instance, people with autosomal dominant forms of BD are often shorter than expected and may have other alterations of the skeleton besides short digits. Some people with BD type E also have hypertension (high blood pressure). BD may also be present as one finding in a number of different genetic conditions (syndromes).

Diagnosis

The diagnosis of BD is made when a person has shortening of the digits due to lack of normal growth and development of one or more bones in the hands or feet. When the bones are significantly shortened, this is easily noticed in the appearance of the hands and feet. When the shortening is mild, it may only be apparent on x-rays. Some people may not realize that they have BD until told by a physician who has carefully examined their hands and feet.

X-rays of the hands and feet are used to look at the bones in detail. A special analysis of the hand x-rays called a metacarpophalangeal profile is often performed for people with BD. This involves measuring the length of each hand and finger bone. These measurements are then compared to the normal range of sizes for each bone. The metacarpophalangeal profile is used to identify particular patterns of BD. X-rays may also reveal other bone changes that help to pinpoint a specific type of BD or another genetic condition. If a person has short stature or other

bone changes, a series of x-rays of the entire skeleton (skeletal survey) may be recommended.

Since BD is often inherited, detailed information about a person's relatives can be very important in evaluating someone with BD. A geneticist may wish to examine other family members or obtain x-rays of their hands and feet. Because BD can occur in a variety of genetic conditions, a geneticist evaluating someone with BD will usually review his or her medical history and perform a detailed physical examination. The presence of other physical differences or medical problems may indicate that the brachydactyly is part of another condition rather than an isolated finding.

Laboratory tests are usually not helpful in diagnosing BD when it is an isolated finding. Although the genes for BD types B, C, D, and E are known, testing of these genes is not routinely available or usually necessary. If a person with BD has signs or symptoms of another underlying condition, certain laboratory tests may be recommended. These tests may identify other associated medical problems or help to pinpoint a specific diagnosis.

Treatment and management

Many people who have BD are perfectly healthy and do not require any specific treatment for their hands and feet. When use of the hands is impaired, physical therapy or hand exercises may improve grip strength or flexibility. Evaluation by an orthopedist or physical therapist may also be helpful for people who have trouble walking comfortably due to bone changes in the feet. Surgery can be used to lengthen the hand or foot bones in some severe forms of BD. Surgery may also be helpful for people who have significant clinodactyly, syndactyly, or symphalangism. For most people with BD, however, surgery is not needed. If BD is associated with other medical problems, such as hypertension, specific treatments for these problems may be indicated.

Prognosis

Isolated BD generally has an excellent prognosis. When BD is associated with other health problems or is part of another condition, the overall prognosis depends upon the nature of the associated condition.

Branchiootorenal (BOR) syndrome

Definition

Branchiootorenal (BOR) syndrome is an autosomal dominant condition characterized by ear abnormalities, hearing loss, cysts in the neck, and kidney problems.

Description

The name branchiootorenal syndrome describes the body systems most commonly affected by this genetic disorder. The term "branchio" refers to the abnormalities of the neck found in individuals with this syndrome. Cysts (lumps or swellings that can be filled with fluid) and fistulas (abnormal passages from the throat to the skin) in the neck occur frequently. The term "oto" refers to the ear disorders associated with the syndrome. For example, the outer ear can be unusual in appearance. Hearing loss is also common. Finally, the term "renal" stands for the kidney problems commonly seen in patients with this condition. These can be very mild or very severe, as can any of the symptoms associated with this disorder.

Dr. M. Melnick first described BOR syndrome in 1975. Another name for BOR syndrome is Melnick-Fraser syndrome. Individuals with BOR syndrome typically have physical differences that are present at birth (congenital). These birth defects are caused by a change (mutation) in a gene.

Genetic profile

Mutations in the *EYA1* gene are found in 40% of those with a clinical diagnosis of BOR syndrome. The *EYA1* gene is located on chromosome 8. Mutations in the *SIX5* gene on chromosome 19 account for about 5% of those with the diagnosis. Mutations in the *SIX1* gene on chromosome 1 have been found in a few families. It is likely that there are other causative genes for BOR syndrome that have not been identified yet account for the

Branchiootorenal syndrome: pedigree analysis chart (Gale)

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Bilateral—Related to or affecting both sides of the body or both of a pair of organs.

Cleft palate—A congenital malformation in which there is an abnormal opening in the roof of the mouth that allows the nasal passages and the mouth to be improperly connected.

Congenital—Refers to a disorder that is present at birth.

Cyst—An abnormal sac or closed cavity filled with liquid or semi-solid matter.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

Ear tags—Excess pieces of skin on the outside of the ear.

Fistula—An abnormal passage or communication between two different organs or surfaces.

Gene—A building block of inheritance, which contains the instructions for the production of a

particular protein. It is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Gustatory lacrimation—Abnormal development of the tear ducts causing tears when chewing.

Lacrimal ducts—Tear ducts.

Microtia—Small or underdeveloped external ears.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Preauricular pits—Small pits in the skin on the outside of the ear.

Renal agenesis—Absence or failure of one or both kidneys to develop normally.

Renal hypoplasia—Abnormally small kidneys.

Unilateral—Refers to one side of the body or only one organ in a pair.

Variable expressivity—Differences in the symptoms of a disorder between family members with the same genetic disease.

remaining families. The exact function of these genes is unknown, but mutations in them disrupt normal development, producing the physical differences common to BOR syndrome. Mutations in these genes can affect the normal development of the ear, kidney, and the branchial arches. The branchial arches are tissues that develop very early in pregnancy and are involved in the formation of the face and neck.

BOR syndrome is inherited in an autosomal dominant manner. This means that only one gene in the pair must be mutated in order for the individual to be affected. The characteristics of the syndrome can be extremely variable in severity from person to person with the condition. If a child inherits an abnormal gene from a parent, the signs of the disorder can be very different between the parent and the child. This is called *variable expressivity*. For example, a parent who has a very mild form of BOR syndrome can have a severely affected child. The reverse situation can also occur. A mutation in one of the causative genes may be inherited from a parent with BOR syndrome. Still, it can also occur by chance in an individual without a family history of BOR syndrome.

Genetic testing for the three genes known to cause BOR syndrome is available. The recommended testing

strategy is to study the DNA sequence of the *EYAI* gene first, and then if no mutations are found, to perform a chromosome study, looking for structural rearrangements in the areas of the three known genes. A chromosome study may also detect deletions or duplications of genetic material involving the three genes. If no changes are found, then mutation analysis of the other two genes is recommended. The clinical features of the syndrome in a person may help guide testing. Those with mutations in the *EYAI* gene are likely to have a milder set of clinical features. Those with *SIX1* are less likely to have renal disease and those with *SIX5* may have normal hearing.

Demographics

BOR syndrome occurs 1 in every 40,000 live births, although the condition is likely underdiagnosed. BOR syndrome is seen in all ethnic groups and cultures. It also affects males and females equally. One study suggested that 2% of individuals with severe hearing loss have BOR syndrome.

Signs and symptoms

The characteristics associated with BOR syndrome are highly variable. Some individuals with BOR syndrome

have many physical deformations. Other individuals with BOR syndrome have a few minor physical differences. The birth defects can occur on only one side of the face (unilateral) or be present on both sides (bilateral).

Abnormal development of the external ear is the most common characteristic of BOR syndrome. The ears may be smaller than normal (microtia) and may have an unusual shape. Ear tags (excess pieces of skin) are present on the cheek next to the ear in 13% of those with the condition. Preauricular pits (small pits in the skin on the outside of the ear) are found in 80% of patients with BOR syndrome. Hearing loss is present in 90% of individuals with BOR syndrome and this loss may be mild or severe. The type of hearing loss most common is mixed hearing loss followed by conductive and sensorineural. There may also be malformations in the inner or middle ear or the external auditory canal.

The most distinctive finding in individuals with BOR syndrome is the presence of cysts or fistulas in the neck region due to abnormal development of the branchial arches. These cysts and fistulas can be filled with or discharge fluid.

Approximately two-thirds of individuals with BOR syndrome also have kidney abnormalities. These abnormalities can be very mild and cause no health problems or they can be very severe and life-threatening. The kidneys can be smaller than normal (renal hypoplasia), abnormally shaped, malfunctioning, or totally absent (renal agenesis).

Other less common characteristics associated with BOR syndrome include cleft palate, facial nerve paralysis, and small lower jaw. Some exhibit abnormalities of the tear ducts. The tear ducts (lacrimal ducts) may be absent or abnormal. Some patients with BOR syndrome express uncontrollable tears while chewing (gustatory lacrimation).

Of the features associated with BOR syndrome, some are considered major while others are considered minor when making a diagnosis. The major criteria are:

- second branchial arch anomalies
- deafness
- preauricular pits
- changes in the shape of the outer ear
- renal anomalies

The minor criteria are:

- changes in the external auditory canal
- middle ear anomalies
- inner ear anomalies
- preauricular tags
- facial asymmetry or palate abnormalities

QUESTIONS TO ASK YOUR DOCTOR

- Is it possible to detect my child's having branchiootorenal syndrome with a prenatal test?
- Are there any risks associated with such a test?
- What abnormal characteristics are associated with branchiootorenal syndrome?
- Would my child be able to live a normal life if born with branchiootorenal syndrome?

Diagnosis

The diagnosis of BOR syndrome is made when an individual has the common clinical characteristics associated with the condition. An individual does not need to have all three components of the disorder in order to be diagnosed with the condition. The usual method of diagnosis is that a person is considered affected if they have three or more major criteria or two major and one minor criteria. If a person has an affected first-degree relative, then one major feature is enough to make the diagnosis.

Differential diagnosis

There are a number of other syndromes with overlapping clinical features that should be considered when diagnosing a person with BOR syndrome. When branchial and facial features are present but not renal, then brachiofacial syndrome is a possibility. If branchial and renal features are present but no hearing loss or ear abnormalities, branchiooculorenal syndrome is a possibility, especially if certain eye abnormalities are present. Goldenhar, Treacher Collins, Townes-Brocks, and CHARGE syndromes all have features similar to BOR syndrome. A careful examination by a medical geneticist can ensure the best clinical diagnosis is made and appropriate genetic tests are offered.

Treatment and management

Once a child is diagnosed with BOR syndrome, additional tests should be performed. A hearing evaluation is necessary to determine if there is hearing loss. If hearing loss is evident, the child should be referred to a hearing specialist. Hearing tests may need to be performed on a regular basis. Hearing aids or cochlear implants may be considered. Those with hearing loss should also be offered an appropriate educational setting. Speech therapy may also be helpful. An ultrasound of the kidney may be necessary, due to the increased risk for birth defects in these areas. If renal problems are present, there

may be a need for renal dialysis or surgery. If end-stage renal disease is reached, then a renal transplant may be considered. A nephrologist or kidney specialist should be involved in the care of a person with BOR syndrome. Finally, minor surgery may be required to correct the branchial cysts and fistulas commonly found in BOR syndrome.

Prognosis

The prognosis for individuals with BOR syndrome is very good. Individuals with BOR syndrome typically have a normal lifespan and normal intelligence. There are several organizations listed at the end of this entry where individuals and families with BOR syndrome may connect with other families, learn more about the condition, find recent research and useful resources, and become involved in advocacy.

Breast cancer

Definition

Breast cancer is a disease in which abnormal breast cells begin to grow uncontrollably, forming tumors. It often shows up as a breast lump, breast thickening, or skin change.

Description

The breasts are areas of tissue located on the front chest wall, and they are essentially part of the skin. In their structure and function, they are like specialized sweat glands in that they can produce and secrete fluids (milk). They are made of ductal tissue, supporting connective tissue, and fat. The breasts naturally drain fluid through the lymph channels to the axillary lymph nodes, located in the armpit areas. Within the breasts are intricate structures of ducts and lobules, which are channels and areas that create and transport milk during lactation.

Excluding skin cancers, breast cancer is the most common cancer among women and one of the leading causes of death in women in their middle years of life. Male breast cancer is rare and accounts for less than 1% of all breast cancers. Both genetic and environmental factors are thought to cause breast cancer. Of all breast cancer diagnoses, only approximately 5% to 10% are caused by hereditary factors such as specific alterations in breast cancer susceptibility genes or by a genetic cancer syndrome. In these instances, individuals may have a strong family history of cancer and the cancers may be diagnosed at an earlier age than usual.

Breast cancers vary in their type and size. This can be determined by a breast biopsy. Breast cancer may commonly be detected by a mammogram, a physician's clinical breast examination (CBE), or a patient's own breast self-examination (BSE). Breast cancer, if it is the first cancer developed, may sometimes metastasize (spread) to other organs, such as the liver, bone, lungs, skin, or brain. The breasts may also be the site of metastasis from other primary cancers.

Breast cancer may present as a lump or other change within the breast. As with other types of cancer, the initial diagnosis may be unexpected. Each cancer has a unique prognosis, which will affect the patient's concern. If an individual has a very strong family history of breast cancer, the diagnosis may be somewhat expected but no less emotionally taxing. Treatment and management of the cancer may be extremely exhausting, painful, and stressful for the patient and his or her family.

Genetic profile

Cells in breast tissue normally divide and grow according to controls and instructions of various genes. If these genes have changes within them, the instructions for cellular growth and division may go awry. Abnormal uncontrolled cell growth may occur, causing breast cancer. Therefore, all breast cancers are genetic, because they all result from changes within genes. However, most breast cancers occur later in life after years of exposure to various environmental factors that can cause alterations (such as the body's own hormones, asbestos, or smoking).

A small proportion of breast cancer is caused by inherited genetic alterations (pathogenic variants). In 1994, a breast cancer susceptibility gene known as *BRCA1* (location 17q21), was identified. The next year, the discovery of *BRCA2* (location 13q12) followed. Women with alterations in these genes have an increased risk for breast and ovarian cancer, and men have an increased risk for prostate cancer. Men with a *BRCA2* alteration have an increased risk for breast cancer. Slightly increased risks for colon and pancreatic cancers (in men and women) are associated with *BRCA2* alterations.

BRCA1 and *BRCA2* alterations are inherited in an autosomal dominant manner; an individual has one copy of a *BRCA* alteration and has a 50% chance of passing it on to each of his or her children, regardless of that child's gender. Nearly all individuals with a *BRCA* alteration (or other gene alterations associated with breast cancer susceptibility) have a family history of the alteration, usually a parent. In turn, they also may have a very strong family history of breast, ovarian, prostate, colon, and/or pancreatic cancers. Aside from *BRCA1* and *BRCA2*, there are other genes that when altered increase an individual's susceptibility to breast cancer, such as *CDH1*, *PTEN*, *STK11*, and *TP53*. Other genes exist that convey a smaller risk for breast cancer while conveying a larger risk for other cancers.

BRCA1 and *BRCA2* are thought to function as "tumor-suppressor genes," meaning that their normal role is to prevent tumors from forming. Specifically, they control cellular growth and division, all the while preventing the overgrowth that may lead to cancer. Alterations in tumor-suppressor genes, such as *BRCA1* and *BRCA2*, would naturally lead to an increased risk of developing cancer. However, this risk is not 100%.

A doctor assisting a patient undergoing a mammogram to test for breast cancer (Tyler Olson/Shutterstock)

Not only variations of the *BRCA1* and *BRCA2* genes increase the risk of developing breast cancer. Variations in *CDH1*, *PTEN*, *STK11*, and *TP53* have also recently been shown to increase risk. Mutations in these genes cause syndromes that greatly increase the chance of developing several types of cancer over a person's lifetime. Some of these syndromes also include other signs and symptoms, such as the growth of noncancerous (benign) tumors. Some research suggests that inherited variants of the *ATM*, *BARD1*, *BRIPI*, *CHEK2*, *NBN*, *PALB2*, *RAD50*, and *RAD51* genes, as well as certain versions of the *AR* gene, may also be associated with breast cancer risk.

A 2021 study sought to better define the genes most associated with breast cancer risk. Researchers designed a panel with 34 known or suspected genes that increase susceptibility and compared with data to estimate breast cancer risk. Nine of the genes had a strong association. These include:

- *ATM*
- *BRCA1*
- *BRCA2*
- *CHEK2*
- *PALB2*
- *BARD1*
- *RAD51C*
- *RAD51D*
- *TP53*. As a result, the authors suggested that these genes be included in testing panels for predicting breast cancer risk, and further defined how protein-truncating variants in some genes affect risk for improved genetic counseling.

There are rare genetic cancer syndromes that may include breast cancer. As a group, these comprise less

than 1% of all breast cancer diagnoses. In these instances, an individual may have other health problems (unrelated to cancer) and a family history of a wide variety of cancers and symptoms. These health problems can initially appear unrelated, but they may be caused by alterations (pathogenic variants) in a specific gene.

Demographics

In 2021, the Centers for Disease Control and Prevention (CDC) reported that in 2017, more than 250,520 women and 2,276 men had been diagnosed with breast cancer in the United States. That year, 42,000 women and 510 men died from breast cancer. According to the American Cancer Society (ACS), breast cancer is the most common cancer among American women except for skin cancers. The chance of developing invasive breast cancer at some time in a woman's life is about 13 percent. In 2021, the ACS estimated that 281,550 new cases of invasive breast cancer would be diagnosed among women in the United States. After increasing during the 1980s and 1990s, female breast cancer incidence rates decreased by 3.5% per year from 2001 to 2004 and then began to rise slightly again. Breast cancer is the second leading cause of cancer death in women, exceeded only by lung cancer. The chance that breast cancer will be responsible for a woman's death is about 1 in 36 (about 3%). Death rates from breast cancer have been declining since about 1990, with larger decreases in women younger than age 50. These decreases are believed to be the result of earlier detection through screening and increased awareness, as well as improved treatment. In 2020, there were about 3.8 million breast cancer survivors in the United States.

According to ACS, white women are slightly more likely to develop breast cancer than are African American women, but African American women are more likely to die of this cancer. This disparity seems to be because African American women tend to have more aggressive tumors, although the cause is unknown. Asian, Hispanic, and Native American women have a lower risk of developing and dying from breast cancer.

Signs and symptoms

Various symptoms may bring someone to medical attention in order to investigate the possibility of breast cancer. These may include a breast lump that persists, as compared to one that only appears at certain times of a woman's menstrual cycle (which is more common). Other signs include changes from the normal breast shape, pain, itchiness, a turned-in nipple, fatigue, or unexplained weight loss. Fluid leaking from the nipple is a particular concern if the woman is not pregnant.

Sometimes individuals may feel a breast lump or change while examining their own breasts, or a physician may note it on a CBE. Additionally, it may be seen on a screening mammogram. It is important to note that not all breast lumps or breast changes signify cancer—they may be benign growths or cysts that need to be removed or drained.

Signs of a possible *BRCA1* or *BRCA2* alteration in a family, signifying hereditary breast or ovarian cancer, include:

- several relatives with cancer
- close genetic relationships between people with cancer, such as parent–child, sibling–sibling
- early ages of cancer onset, such as before ages 45 and 50
- an individual with both breast and ovarian cancer
- an individual with bilateral or multifocal breast cancer
- the presence of ovarian, prostate, colon, or pancreatic cancers in the same family
- case(s) of breast cancer in men

Suspicion of a *BRCA* alteration may be raised if someone has the above features in their family and is of a particular ethnic group, such as an Ashkenazi Jew. This is because specific *BRCA1* and *BRCA2* alterations are known to be more common in that group of individuals.

Diagnosis

Once a suspicious breast abnormality has been found, the next step is to determine whether it is breast cancer. A mammogram can identify an area of increased breast density, which is a common sign of a malignant tumor. Women in their 20s and 30s naturally have denser breasts, so mammograms may not be as effective in that age group, because the increased breast density associated with a tumor is difficult to see. Breast ultrasound, a way of visualizing the breast tissue using sound waves, can be helpful in younger women, because breast density is not a large factor in its effectiveness. A breast biopsy can determine specifically whether the breast tissue has undergone a benign or malignant change, because the breast tissue is studied directly under a microscope. Sometimes, biopsies are performed with a very thin needle (known as fine needle aspiration) or with x-ray guidance using a thicker needle (known as a core needle biopsy).

Newer techniques have improved breast cancer screening and diagnosis. Digital mammograms have ended the need for film. The digital images provide finer detail and allow the images to be rotated in order to get several different views of the breasts. Magnetic resonance imaging (MRI) uses magnetic energy to create an image. Its effectiveness is currently the subject of research

studies. MRI is not widely used, because it is expensive. Still, MRI often provides very detailed imaging of tumors.

A U.S. Supreme Court decision in 2013 that banned the patenting of human genes (including *BRCA*) led to a rapid increase in the number of laboratories that offer molecular DNA testing for breast cancer susceptibility genes, including *BRCA1* and *BRCA2*. The development of new DNA sequencing techniques called next-generation sequencing (NGS) has enabled the development of multigene panel testing for breast cancer susceptibility genes.

Next-generation DNA sequencing allows parallel sequencing or reading of millions of short pieces of DNA simultaneously. Before this new technology, genetic testing usually started with the most commonly involved genes (*BRCA1* and *BRCA2*) and then proceeded to less likely genes only if clinical suspicion was still high enough to warrant further testing. However, multigene panels allow testing of multiple breast cancer genes at the same time without substantially increasing the cost. In addition, they allow testing for other inherited cancer syndromes that might have clinical overlap with inherited breast cancer.

Genetic testing using next-generation sequencing allows for the analysis of multiple genes at one time (multigene panel testing). As gene sequencing became more affordable, larger panels became possible. A 2019 study reported that analyses can vary from six to more than

A scanning electron micrograph of a breast cancer cell.
(Cultura RM/Alamy)

Breast cancer: pedigree analysis chart (Gale)

100 genes. Multigene panels for breast cancer susceptibility genes may contain genes that confer different risks for breast cancer (high, moderate, low) or genes associated with different genetic syndromes linked to breast cancer (e.g., Li-Fraumeni syndrome).

In general, multigene panel testing decreases cost and improves efficiency of testing. However, it can increase patient anxiety. Results of multigene panel testing can be more difficult to interpret, with more variants of unknown significance (VUS) being detected. In addition, not all of the alterations (pathogenic variants) have well-established cancer-prevention guidelines. However, as more testing and research is performed, these disadvantages will lessen.

With any method of DNA testing, it is best to begin the testing process with an individual who has survived breast and/or ovarian cancer, because tests are more likely to find an alteration in a cancer survivor than in someone who has not had cancer. A result is abnormal (or “positive”) if a known cancer-causing *BRCA* alteration (pathogenic variant) is found. If an alteration is found, it is assumed to have caused the cancer(s) in the tested, affected individual. That individual may also identify new cancer risks from the positive result. For example, if a woman survived breast cancer and was found to have a *BRCA* alteration through testing, she would now be at an increased risk to develop ovarian cancer as well as a second breast cancer.

For people who go through testing and are not found to have a *BRCA* alteration (a “negative” result), this result is not informative. There are several possibilities for a negative result. First, there could be a *BRCA* alteration

in the family, although the person did not inherit it. In that case, the cancer would be due to reasons unrelated to *BRCA1* and *BRCA2*. Additionally, they could have an alteration in an unknown gene for which there is no testing available. Lastly, they could have a *BRCA1* or *BRCA2* alteration that is undetectable by available testing methods.

There is a possibility that individuals may have an unknown alteration in one of their *BRCA* or other inherited breast cancer susceptibility genes. This is termed a variant of unknown significance or VUS. In such a scenario, a change in the DNA is identified, but its significance is unclear. Therefore, it is unknown whether the gene change causes cancer. In these situations, the results are most often considered uninformative, until more information about the alteration becomes available in the future.

Once an alteration (pathogenic variant) is identified, other at-risk relatives, both affected and unaffected, can pursue targeted analysis for the confirmed familial alteration. This is much quicker and far less expensive than the initial analysis.

Unaffected individuals who test positive for a known alteration in the family are at a significantly increased risk to develop the associated cancers. A woman’s risks associated with a *BRCA1* alteration are 57% to 87% for breast cancer by age 70 and 24% to 54% for ovarian cancer by age 70. A man’s risk with a *BRCA1* alteration is about 7% for prostate cancer by age 70. A woman’s risks with a *BRCA2* alteration are 41% to 84% for breast cancer by age 70, and 11% to 27% for ovarian cancer by age 70. Up to 7% of men with *BRCA2* alteration develop breast

cancer. Furthermore, they are at a slight or moderate risk for prostate cancer. For *BRCA2* in men and women, there is an increased risk for colon and pancreatic cancers. Information about lifetime risks associated with alterations in other breast cancer susceptibility genes varies depending upon the gene involved.

When a person who has not had cancer has test results that are negative for a known familial *BRCA* alteration, they are lowered to the general risk of developing associated cancers. For example, the lifetime risk for a woman to develop breast cancer has a 12% estimate. This lowered expected risk is because he or she did not inherit the genetic alteration causing cancer in his or her family.

Everyone should receive proper genetic counseling before pursuing any DNA testing. This counseling should include questions about what the patient hopes to learn from the testing. Many people are not aware of the testing limitations and may be expecting a clear “yes/no” answer from the results. Asking people what they hope to learn from testing allows the counselor an opportunity to provide them with accurate facts, such as the possibility of a result that is not informative. Common motivations for getting tested include the need to make informed medical decisions, financially planning for the future, or just “wanting to know” about cancer risk.

Genetic testing for cancer susceptibility often triggers strong emotional responses. It is important to find out about an individual’s support system before beginning testing. Having a close friend, family member, or religious leader to talk with is often helpful for people who are pursuing testing. Someone who tests positive may be concerned because his or her risks for cancer are now higher than they were before the testing. Additionally, someone may feel empowered by the knowledge, because they can better plan for medical procedures. Someone with a family history of a *BRCA* alteration may feel relief if they test negative, because they initially assumed that they would develop cancer. Alternately, someone who tests negative in this situation may feel “survivor guilt” for not having inherited the altered gene in the family. All of these feelings may change the way an individual interacts with his or her family and friends. People may not be aware of the emotional changes that can occur from learning about cancer risk through genetic testing.

It is important to discuss the possibility of insurance coverage for the testing, particularly because testing is so expensive. Insurance companies might not routinely cover the testing unless a physician or genetic counselor describes the need for testing in a letter. Some companies are willing to cover the testing without wanting to know the results.

KEY TERMS

Alteration—Change or mutation in a gene, specifically in the DNA that codes for the gene.

Benign—Referring to a noncancerous tumor that does not spread and is not life-threatening.

Bilateral breast cancer—Cancer of both breasts, caused by two separate cancer processes.

Bile—A substance produced by the liver and concentrated and stored in the gallbladder. Bile contains a number of different substances, including bile salts, cholesterol, and bilirubin.

Breast biopsy—A small sample of tissue taken from the breast and studied to diagnose and determine the exact type of breast cancer.

Breast self-exam (BSE)—Examination by an individual of their own breasts.

CA-125 (Carbohydrate antigen 125)—A protein that is sometimes high when ovarian cancer is present. A blood sample can determine the level of CA-125.

Clinical breast exam (CBE)—Examination of the breasts, performed by a physician or nurse.

Malignant—Referring to a tumor growth that spreads to another part of the body, usually cancerous.

Mammogram—A procedure in which both breasts are compressed/flattened and exposed to low doses of x-rays, in an attempt to visualize the inner breast tissue.

Metastasis—The spreading of cancer from the original site to other locations in the body.

Multifocal breast cancer—Multiple primary cancers in the same breast.

Primary cancer—The first or original cancer site before any metastasis.

Tumor—An abnormal growth of cells. Tumors may be benign (noncancerous) or malignant (cancerous).

Treatment and management

Breast cancer treatment is determined by the exact size and type of cancer, so it is often unique to an individual. Increasingly, staging of breast cancer and treatment decisions also consider certain genetic results that indicate more aggressive or less aggressive cancer. Treatment may include surgeries, such as a lumpectomy (removal of the breast lump) or mastectomy (removal of the entire breast). Breast reconstruction (re-creation of the breast)

by plastic surgery is an option that some individuals may pursue.

Chemotherapy, or using strong chemicals to kill fast-growing cells, is a common treatment. Side effects from chemotherapy may include nausea, vomiting, hair loss, exhaustion, and sores in the mouth. Symptoms associated with menopause (such as hot flashes and the absence of menstrual periods) may occur. Additionally, menopause may actually begin because of chemotherapy. Radiation therapy is another common form of treatment, in which directed radioactive waves are used to kill fast-growing cells. Some side effects of radiation therapy are dry and itchy skin, rashes, exhaustion, nausea, and vomiting.

Sometimes, medications such as tamoxifen are used to prevent a breast cancer from coming back. Tamoxifen is often used for five years following a breast cancer diagnosis to actively prevent a recurrence. It is only effective in specific types of breast cancer, which again are unique to each individual. Some side effects of tamoxifen include beginning menopause as well as an increased risk for uterine cancer. Other drugs, such as raloxifene, are currently being studied for breast cancer prevention, because they may be able to do the same things as tamoxifen but without the side effects. Research studies are under way to determine whether tamoxifen or raloxifene can reduce the risk of breast cancer in women with *BRCA* or other breast cancer susceptibility gene alterations.

An example of a screening program for women at high risk to develop breast cancer includes:

- BSEs monthly starting in early adulthood (about 20 to 25 years of age)
- CBEs every six months or yearly starting at age 25 to 35
- mammograms yearly starting at age 25 to 35

Exact screening guidelines may vary among physicians. For men with a *BRCA2* alteration, breast cancer screening is recommended, though no formal program is specifically recommended.

In addition to screening, women with *BRCA1* or *BRCA2* alterations or other high-risk gene mutations should know about their preventive surgery options. They may consider having their healthy breasts and/or ovaries removed, in order to reduce their risks of developing breast and/or ovarian cancer. Women may be more agreeable to an oophorectomy, because ovarian cancer is difficult to detect. Surgeries may greatly reduce a woman's cancer risk, but they can never eliminate the risk entirely.

There are support and discussion groups available if someone has cancer or is at risk for cancer. These may be invaluable to those who feel alone in their situation.

QUESTIONS TO ASK YOUR DOCTOR

- What type of breast cancer do I have?
- What stage of breast cancer do I have?
- What treatment options are available for my breast cancer?
- What are the risks and benefits of each possible type of treatment?

Clinical trials

Clinical trials for the treatment of breast cancer and the evaluation of new drugs are sponsored by the National Institutes of Health (NIH) and other agencies. Some of these trials address treatment options, and many studies look specifically at hereditary breast cancer or the genetics of breast cancer.

Prognosis

The type and size of breast cancer developed largely determine the overall prognosis. Those with larger tumors and those with a type of breast tumor that does not usually respond to treatment may have a less hopeful outcome. Once cancer has spread to other areas of the body, the prognosis worsens, because the cancer is more difficult to treat. It may also be more likely to continue spreading to other areas of the body.

For cancer-free individuals identified to have *BRCA* (or other gene alterations associated with breast cancer susceptibility), it is important to remember that they are at an increased risk to develop the associated cancers, but that the risk is *not* 100%. Though people with *BRCA* or other breast cancer susceptibility gene alterations may feel “destined” to develop cancer, it is by no means a certainty. It is also important to emphasize that breast cancer screening techniques and treatments are constantly being evaluated and improved.

Bruton agammaglobulinemia

Definition

Bruton agammaglobulinemia is an X-linked genetic condition caused by a mutation in the key enzyme Bruton’s tyrosine kinase (BTK) that is needed for proper function of the immune system. People who have this disorder have low levels of protective antibodies and do not produce mature B cells, making them vulnerable to repeated and potentially fatal infections.

Description

The body’s ability to resist and fight off infections by microorganisms like bacteria, viruses, parasites, and fungi depends on the function of the immune system. The immune system is composed of specialized cells whose function is to recognize organisms that are foreign to the body and destroy them. B cells are one set of specialized cells that fight infection. B cells circulate in the bloodstream and produce proteins called antibodies that are made of different classes of immunoglobulin. Immunoglobulin antibodies are then released into the bloodstream where they attach to invading microorganisms. Antibodies are specially designed to bind specific microorganisms, very similar to a lock and key. Once the antibodies attach to the microorganism, they trigger other specialized cells of the immune system to attack and destroy the invader, thus preventing or fighting an existing infection.

In order for antibodies to be produced by the body, the B cells must develop and mature so they are capable of producing the infection-fighting antibodies. When this process does not occur normally, the immune system cannot work properly to fight off infection, a state known as immunodeficiency. Bruton agammaglobulinemia (also called X-linked agammaglobulinemia, congenital agammaglobulinemia, or LXA) is an inherited immunodeficiency characterized by the failure to produce mature B cells or antibodies. The abnormality in this disorder resides in Bruton tyrosine kinase (BTK, also known as

BPK or ATK), an enzyme needed for the maturation of B cells. As a result, people with this condition have low levels of mature B cells and the antibodies that they produce, making them vulnerable to frequent and sometimes dangerous infections.

Bruton agammaglobulinemia was discovered by physician Colonel Ogden C. Bruton in 1952 and was the first immunodeficiency disease to be identified. Bruton's patient was a four-year-old boy who was admitted to Walter Reed Army Hospital because of an infected knee. The child recovered well when Bruton gave him antibiotics, but over the next four years had multiple infections. At that time a new instrument was installed in the hospital's laboratory that was able to measure levels of antibodies in the bloodstream. At first the technician believed the machine was defective because it did not detect gammaglobulins (the building blocks of antibodies) in the boy, but Bruton recognized the significance of this finding and remarked, "Things began to click then. No gammaglobulins; can't build antibodies."

Genetic profile

Bruton agammaglobulinemia is inherited in an X-linked recessive manner and so affects males more often than females. Females have two X chromosomes, which means they have two copies of the *BTK* gene, whereas males only have one X chromosome and one copy of the *BTK* gene. If a male has a mutated *BTK* gene, he will have Bruton agammaglobulinemia. If a female has one mutant *BTK* gene, she will be a carrier and will be able to pass the mutated gene on to her children. If her son inherits the altered gene, he will have the disease; if her daughter inherits the altered gene, she will be a carrier like her mother. Alternatively, if her son does not inherit the mutated *BTK* gene, he will not be affected and will not pass the altered gene on to his children because fathers only pass a Y chromosome to their sons and an X chromosome to their daughters.

Mutations in the gene that codes for *BTK* (located at Xq21.3-22) are responsible for the disease. Over 250 different mutations in *BTK* have been identified; they are spread almost evenly throughout the *BTK* gene. While this abnormal gene can be passed from parent to child, in half of the cases a child will show the disease without having a carrier. This is because new mutations in the *BTK* gene can occur and then be passed on to the affected individual's children.

Demographics

Bruton agammaglobulinemia occurs in all racial groups, with an incidence between 1 in 50,000 and 1 in 100,000 individuals.

KEY TERMS

Antibiotics—A group of medications that kill or slow the growth of bacteria.

Antibody—A protein produced by the mature B cells of the immune system that attaches to invading microorganisms and targets them for destruction by other immune system cells.

B cell—A specialized type of white blood cell that is capable of secreting infection-fighting antibodies.

Bruton tyrosine kinase (BTK)—An enzyme vital for the maturation of B cells.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Immune system—A major system of the body that produces specialized cells and substances that interact with and destroy foreign antigens that invade the body.

Immunodeficiency—A defect in the immune system, leaving an individual vulnerable to infection.

Immunoglobulin—A protein molecule formed by mature B cells in response to foreign proteins in the body; the building blocks for antibodies.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual or manifest as disease and can be transmitted to offspring.

Vaccine—An injection, usually derived from a microorganism, that can be injected into an individual to provoke an immune response and prevent future occurrence of an infection by that microorganism.

X chromosome—One of the two sex chromosomes (the other is Y) containing genetic material that, among other things, determines a person's sex.

Signs and symptoms

Children with Bruton agammaglobulinemia are born healthy and usually begin to show signs of infection in the first three to nine months of life, when antibodies that come from the mother during pregnancy and early breastfeeding disappear. In 20%–30% of the cases, patients may have slightly higher levels of antibodies present and symptoms will not appear until later in childhood.

Patients with Bruton agammaglobulinemia can have infections that involve the skin, bone, brain, gastrointestinal tract, sinuses, eyes, ears, nose, airways to the lung, or the lung itself. In addition, the bacteria may migrate from the original site of infection and enter the bloodstream, leading to an overwhelming infection of the body that is potentially fatal.

Besides immunological signs of Bruton agammaglobulinemia, other physical symptoms include slow growth, wheezing, small tonsils, and abnormal levels of tooth decay. Children may also develop unusual symptoms such as joint disease, destruction of red blood cells, kidney damage, and skin and muscle inflammation. Increased incidences of cancers, such as leukemia, lymphoma, and colon cancer, have been associated with Bruton agammaglobulinemia in a small percentage of people.

Bacteria that are easily destroyed by a normal-functioning immune system can cause infections in individuals with Bruton agammaglobulinemia. The most common bacterial species responsible for these infections include *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Neisseria meningitidis*, *Klebsiella pneumoniae*, *Hemophilus influenzae*, and *Mycoplasma* species. Chronic stomach and intestine infections are often linked to the parasite *Giardia lamblia*.

Patients with Bruton agammaglobulinemia can successfully defend themselves against infection from viruses and fungi because other aspects of the immune system are still functional. However, there are some notable exceptions—people with this disorder are still vulnerable to the hepatitis virus, poliomyelitis virus, and echovirus. Echovirus is particularly troubling because it can lead to progressive and fatal infections of the brain, joints, and skin.

Diagnosis

Recurrent infections or infections that fail to respond completely or quickly to antibiotics should prompt a diagnostic search for immunodeficiency and Bruton agammaglobulinemia. Another helpful sign of Bruton agammaglobulinemia is the presence of unusually small lymph nodes and tonsils. Additionally, many patients with this disorder have a history of continuous illness where they do not recover between bouts.

When a patient is suspected of having Bruton agammaglobulinemia, the diagnosis is established through the use of several tests. The amount of immunoglobulin is measured in a blood sample from the affected individual by a technique called immunoelectrophoresis. In Bruton agammaglobulinemia, all of the immunoglobulins will

QUESTIONS TO ASK YOUR DOCTOR

- What are the most serious health problems associated with Bruton agammaglobulinemia?
- What treatments are available for Bruton agammaglobulinemia?
- Under what conditions, if any, should my child be expected to have a reasonably normal life as a person with Bruton agammaglobulinemia?
- What support groups are available for individuals with Bruton agammaglobulinemia and their families?

be markedly reduced or absent. There is some difficulty in diagnosing the disease in unweaned infants because immunoglobulins from the mother are still present in the child during the first few months of life.

When the diagnosis is still unclear, further tests can be performed to determine if there has been any response to normal childhood immunizations because patients with Bruton agammaglobulinemia are unable to respond to immunization with antibody production. Confirmation of the diagnosis can be made by demonstrating abnormally low numbers of mature B cells in the blood or by genetic studies that look for mutations in the *BTK* gene. When a diagnosis of Bruton agammaglobulinemia is made in a child, genetic testing of the *BTK* gene can be offered to determine whether the specific gene mutation can be identified. If the mutation is identified, carrier testing can be offered to the mother and other female relatives. In families in which the mother has been identified to be a carrier of a *BTK* gene mutation, diagnosis of Bruton agammaglobulinemia before birth is possible with prenatal genetic diagnosis techniques. In some families, a *BTK* gene mutation cannot be identified and other laboratory techniques may be available to these families, such as linkage studies or X chromosome inactivation studies.

Other diagnostic tests have been advocated to track the ongoing health of the patient with Bruton agammaglobulinemia. X-rays of the sinuses and chest should be obtained at regular intervals to monitor for the early development of infections and to determine whether proper treatment has been established. Lung function tests should also be performed on a regular basis, when the patient is old enough to cooperate. Patients who have ongoing gastrointestinal tract symptoms should be tested for the parasite *Giardia lamblia*.

Treatment and management

There is currently no cure for Bruton agammaglobulinemia and so the goals of treatment are threefold: to treat infection effectively, to prevent repeated infections, and to prevent the lung damage that may result from repeated infections.

The main complication in patients with Bruton agammaglobulinemia is a lack of immunoglobulins, which are the building blocks of antibodies. Treatment focuses on replacing immunoglobulin and thereby providing patients with the antibodies they need to fight infection. Immunoglobulin can be injected into Bruton agammaglobulinemia patients either intravenously or subcutaneously. Treatment with immunoglobulin is given every three to four weeks and is usually effective in preventing infection by various microorganisms. Individuals with Bruton agammaglobulinemia can live relatively normal lives and are at no greater risk for developing other autoimmune disorders.

Side effects from or allergic reactions to immunoglobulin are infrequent, only affecting about 3%–12% of people treated with injections. Symptoms will usually subside if the immunoglobulin is given slowly and the reactions may disappear after receiving the immunoglobulin several times. Patients should not receive live viral vaccines; in some cases Bruton agammaglobulinemia patients can transmit the diseases that they are being vaccinated against.

If infection does occur in a patient with Bruton agammaglobulinemia, antibiotics (medications that kill bacteria) are also given to help fight off the infection. Recurrent or chronic infections will develop in some patients despite the use of immunoglobulin. In these cases antibiotics may be given every day even when there is no infection present, in order to prevent an infection from forming. If chronic diarrhea is experienced by the patient, tests should be performed to look for the parasite *Giardia lamblia* and proper antibiotics should be given to kill the organism.

Preventative techniques are also very important. Children with Bruton agammaglobulinemia should be treated promptly for even minor cuts and scrapes and taught to avoid crowds and people with infections. People with this disorder and their family members should not be given vaccinations that contain live organisms, as the organisms may result in the immunocompromised person contracting the disease that the vaccination is intended to prevent. Referral for genetic counseling is appropriate for female relatives seeking information about their carrier status and for family members making reproductive decisions.

Prognosis

Without immunoglobulin treatment, 90% of patients with Bruton agammaglobulinemia will die by the age of eight years. In most patients who have been diagnosed early and are receiving immunoglobulin on a regular basis, the prognosis is reasonably good. They should be able to lead a relatively normal childhood and need not be isolated to prevent dangerous infections.

While current therapy allows most individuals with Bruton agammaglobulinemia to reach adulthood, the prognosis must be guarded. Paralysis of the legs may result from the poliomyelitis virus. Despite what may appear to be adequate immunoglobulin therapy, many patients develop severe irreversible lung disease. Fatal brain infections have been reported even in patients receiving immunoglobulin therapy, and patients who recover from these infections may be left with severe brain damage. Finally, some patients may develop leukemia or lymphoma.

Campomelic dysplasia

Definition

Campomelic dysplasia is a rare, often lethal genetic disorder characterized by multiple abnormalities, including short limbs, bowed legs, distinctive facial features, and a narrow chest. It is also often associated with abnormal development of the reproductive organs in males. The disorder is also known as campotomelic dysplasia, campomelic dwarfism, and campomelic syndrome.

Description

Campomelic dysplasia is a disorder that affects the bones and cartilage of the body, causing significantly short arms and legs, bowing of the legs, small chest size, and other skeletal (bony) and nonskeletal problems. Some genetic males with campomelic dysplasia have female sex organs. Death often results in the newborn period due to breathing problems related to the small chest size. Campomelic dysplasia is caused by an alteration (mutation) in a gene called *SOX9*. This mutation is usually sporadic (occurs randomly).

Genetic profile

Campomelic dysplasia is caused by an alteration in the *SOX9* gene, which plays a role in bone formation and testicular development. Genes are units of hereditary material found on chromosomes, which are passed from a parent to a child through the egg and sperm. The information contained in genes is responsible for the development of all the cells and tissues of the body.

The *SOX9* gene is located on the long (q) arm of chromosome 17 (one of the 22 non-sex chromosomes) at position 17q24. This gene codes for a protein transcription

factor that plays a role in both bone formation and testis development. Any mutation within the coding region of this gene can cause campomelic dysplasia. The testes are responsible for producing male hormones. Every developing baby in the womb (fetus), whether genetically male (XY) or female (XX), starts life with the capacity to develop either male or female sex organs. After a few weeks, in an XY fetus, the genitals develop into male genitals when male hormones are present. In the absence of male hormones, a female body type with female genitals results.

In individuals with campomelic dysplasia, the *SOX9* gene is altered such that it does not interact normally with the *SRY* gene on the Y chromosome. In normal fetal development, when the *SRY* gene is expressed in the fetus, a series of gene interactions controlled by the *SOX9* gene is initiated and eventually leads to male sex development in the fetus. A mutation in the *SOX9* gene thus results in improper formation of the testes and loss of male hormone production. Thus, individuals who are genetically male (XY) can develop as normal females. This phenomenon is known as sex reversal and occurs in about 75% of genetic males with campomelic dysplasia. Since the *SOX9* gene is also important for proper bone formation, the bones of the body are also affected by the mutation, resulting in short stature, bowed legs, and other problems.

There are usually two normal copies of the *SOX9* gene: one copy of the gene is inherited from the mother and one from the father. Campomelic dysplasia is inherited as an autosomal dominant condition. In this pattern of inheritance, a person needs only one altered gene copy to develop the condition. The alteration in the *SOX9* gene that causes campomelic dysplasia is usually random, which means that some unknown event has caused the *SOX9* gene to become altered in either the sperm of the father or the egg of the mother. When this altered sperm or egg is fertilized, the child that results has campomelic dysplasia. The chance for parents of a child with campomelic dysplasia to have a second child with the same condition is slightly higher than it would be for another

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Autosomal dominant—A pattern of inheritance in which one copy of the altered gene in each cell is sufficient to cause the disorder.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother’s vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Dysplasia—The abnormal growth or development of a tissue or organ.

Fetus—The term used to describe a developing human infant from approximately the third month of pregnancy until delivery. The term “embryo” is used prior to the third month.

Genitals—The internal and external reproductive organs in males and females.

Gonads—The organs that will become either testes (male reproductive organs) or ovaries (female reproductive organs) during fetal development.

Hormone—A chemical messenger produced by the body that is involved in regulating specific bodily functions such as growth, development, and reproduction.

Ovaries—The female reproductive organs that produce the reproductive cells (ova) and female hormones.

Pierre Robin sequence—A malformation of the jaw, mouth, and tongue that includes a cleft palate, a small lower jaw (micrognathia), and a tongue set too far back in the mouth. It is named for Pierre Robin, the French physician who first described the sequence in 1923.

Testes (singular, testis)—The male reproductive organs that produce male reproductive cells (sperm) and male hormones.

Transcription factor—A protein that binds to specific DNA sequences and controls the rate of transcription of genetic information from DNA to messenger RNA.

couple who has not had a child with this condition. A person who has campomelic dysplasia can pass on their altered *SOX9* gene to his or her future children. However, there have not been any reports of individuals with campomelic dysplasia having children.

Demographics

Campomelic dysplasia is a rare condition that affects males and females of all racial and ethnic groups. It is estimated that between 5 and 9 per 10,000 live newborns are affected with this condition. Other estimates fall between 1 in 40,000 and 1 in 300,000 newborns.

Signs and symptoms

Campomelic dysplasia can affect the body in several ways. The English word *campomelic* is derived from two Greek words that mean “bent” and “limb,” and refers to the fact that individuals with campomelic dysplasia typically have curved or bowed legs. Usually there is a dimple in the leg just below the knee. The condition is also characterized by significantly short stature, which is evident from birth.

Other features include very small shoulder blades, a very small chest, a curved and twisted spine (kyphoscoliosis), feet that are often turned inward (clubfoot), dislocated hips, and short fingers and toes. Often there are 11 pairs of ribs instead of the usual 12. In some individuals, the pelvic bones and the bones of the spine can also be affected.

Common features can also include a large head size and distinctive facial features, such as a high forehead; a flat, small face; small chin; low-set ears; and widely spaced eyes. Some individuals have an incomplete closure of the roof of the mouth (cleft palate) combined with an underdeveloped lower jaw (micrognathia) and a tongue that is placed farther back in the mouth than is normal. This combination of features is known as Pierre Robin (pronounced roh-BAN) sequence.

Breathing problems are common in campomelic dysplasia and are often the cause of death in newborns. The breathing problems usually result from the small chest size, small lungs, and narrow airway passages. Those who survive into early infancy frequently have feeding problems and difficulty breathing.

Individuals with campomelic dysplasia may also have heart defects and hearing loss. Some females with the condition have a Y chromosome. Females with campomelic dysplasia who have a Y chromosome are genetically male. However, their sex organs are female and thus they are treated as normal females. The intellect of individuals with campomelic dysplasia is usually normal, although there have been reports of some individuals with developmental disabilities. One survivor, aged 17 at the time of her case report in 1993, was said to have an IQ of 45.

Diagnosis

The diagnosis of campomelic dysplasia is based on the presence of certain clinical features. Prenatal diagnosis can be performed by ultrasound and is based on such visible features as bowing of the femur and tibia (the long bones of the upper and lower legs), an undersized jaw, clubbed feet, a pronounced curvature of the neck, and a bell-shaped chest. Some of the bony abnormalities are more obvious on x-ray. However, radiographic examination is most often performed after birth. The features that suggest a diagnosis of campomelic dysplasia include significantly short stature present from birth, small shoulder blades, 11 pairs of ribs instead of 12, small chest size, bowed legs, and a dimple on the leg below the knee. About 10% of individuals who survive past infancy, however, lack the characteristic bowed legs associated with the disorder. This subtype of the disorder is called acampomelic campomelic dysplasia, or ACD.

The diagnosis of campomelic dysplasia can be confirmed through genetic testing, which requires a blood sample from the affected individual. The genetic test involves identifying the specific alteration in the *SOX9* gene. Parents of an affected child may seek testing for campomelic dysplasia in future pregnancies. This can be performed on the developing baby before birth through amniocentesis or chorionic villus sampling if an alteration in the *SOX9* gene is identified in the previously affected individual. Prenatal testing should be considered only after the gene alteration has been confirmed in the affected individual and the couple has been counseled regarding the risks of recurrence.

Treatment and management

Campomelic dysplasia is associated with a significant risk of death in the newborn period due to the small chest and small lungs. There is no effective treatment to expand the size of the chest. Those who survive into early infancy have feeding problems and often have difficulty breathing. An occupational therapist may be able to assist

QUESTIONS TO ASK YOUR DOCTOR

- Is there a particular pattern of inheritance for campomelic dysplasia?
- What is the prognosis for a child born with campomelic dysplasia, and what factors, if any, affect that prognosis?
- Are there medications or surgical treatments that can be used to deal with the symptoms of campomelic dysplasia?
- Are there support organizations for individuals who are living with campomelic dysplasia and their families?

with the feeding issues. Breathing problems may necessitate that the child be placed on oxygen.

Some individuals with campomelic dysplasia have significant twisting and bending of their spine (kyphoscoliosis), which can interfere with breathing. A bone specialist (orthopedist) should be consulted for advice on potential treatments such as bracing or surgery. An orthopedist should also be consulted regarding the other bony problems such as clubfoot and bowed legs. Individuals with campomelic dysplasia should also have their hearing assessed and their heart examined because of the increased risk of hearing loss and heart defects, respectively.

In females with campomelic dysplasia who have a Y chromosome, the gonads (the organs that later become either ovaries or testes during fetal development) do not develop into normal ovaries. It is generally recommended that they be surgically removed because there is an increased chance for tumors to occur in the gonads when they do not develop properly.

Very few individuals with campomelic dysplasia live beyond the newborn period but most who do are of normal intelligence. During the school years, it may be necessary to make some changes (such as providing the individual with a stepstool in the bathroom) to foster independence. For some, meeting other individuals of short stature may be beneficial. Such groups as the Little People of America (LPA) serve as a source of information and offer opportunities to meet other people facing similar challenges. Individuals with campomelic dysplasia and their families may benefit from genetic counseling, which can provide them with further information on the condition itself and recurrence risks for future pregnancies.

Prognosis

Campomelic dysplasia is associated with a significant risk of death in the newborn period. Most newborns die during the first few hours after birth from breathing problems due to the small chest size and underdeveloped lungs; only 5%–10% survive. A few individuals with campomelic dysplasia live into late adolescence.

Camurati-Engelmann disease

Definition

Camurati-Engelmann disease—also known as diaphyseal dysplasia, diaphyseal hyperostosis, and Engelmann's disease—is a rare genetic condition that affects the bones of the body. The long bones in the arms and legs become abnormally long and other bones in the body may become thickened. The increased bone density throughout the body may cause bone pain (especially in the legs), vision and hearing loss, neurological impairments, skeletal disorders, decreased body mass, weakness, and fatigue.

Description

Despite their strength and durability, human bones are living organisms. Throughout the lifespan, bones are constantly being broken down and rebuilt again without losing their proper size and shape. Diseases that interfere with this delicately orchestrated process (called bone remodeling) can produce pain and restrict freedom of movement. In Camurati-Engelmann disease, which was first described in 1920, the shafts of the long bones in the legs become thicker than normal. The femur (thigh bone) and tibia (shin bone) are primarily affected. These changes often cause severe bone pain and weak muscles in the legs. The weak, aching muscles associated with Camurati-Engelmann disease may result in an unusual walk that resembles a waddle. People with Engelmann may be bow-legged and have thin, elongated legs that look as if they are "wasting away."

Aside from bones in the leg, Camurati-Engelmann disease can cause abnormal changes in other bones. People with Camurati-Engelmann disease may develop scoliosis (in which the spine curves to the left or right side) or lumbar lordosis (a forward curvature of the spine). Camurati-Engelmann disease can also cause bones to become abnormally hardened (a process referred to as sclerosis). This hardening can affect the bones at the base of the skull as well as those in the hands and feet. In rare cases, sclerosis may affect the jaw. Individuals with this disease often experience bone pain, weak muscles, and extreme fatigue.

Thickening of the skull causes increased pressure on the brain and can lead to a variety of neurological problems, including vision and hearing loss, headaches, dizziness (vertigo), ringing in the ears (tinnitus), and facial paralysis. Other features of Camurati-Engelmann disease include decreased body fat and delayed puberty.

Camurati-Engelmann disease can also affect internal organs and sight. The liver and spleen may become

enlarged. Loss of vision may occur if bones near the eye sockets are affected. Some people with Camurati-Engelmann disease report headaches, fatigue, and lack of appetite.

Camurati-Engelmann disease is often referred to as Camurati diaphyseal dysplasia, or progressive diaphyseal dysplasia (PDD). Less common names for the condition include osteopathia hyperostotica scleroticans and multiplex infantilis. Camurati-Engelmann disease was sometimes referred to as ribbing disease in the past but this name is no longer used.

Genetic profile

Camurati-Engelmann disease is inherited in an autosomal dominant pattern, which means one copy of the altered gene in each cell is enough to cause the disorder. An affected individual may inherit the mutation from one affected parent or a new mutation in the gene may occur.

Ten different mutations in the *TGFB-1* gene have been found to cause Camurati-Engelmann disease. Located on the long (q) arm of chromosome 19, the *TGFB-1* gene provides instructions for producing a protein called transforming growth factor beta-1 (TGFB-1). Found throughout the body, this protein helps control several functions: the growth and division of cells in the body, the process by which cells mature, cell movement, and the self-destruction of cells (apoptosis). The TGFB-1 protein is found throughout the body and facilitates development before birth, the formation of blood vessels, the regulation of muscle tissue and body fat development, wound healing, and immune system function. TGFB-1 is found in skeletal tissues where it helps regulate bone growth.

Within cells, the TGFB-1 protein is normally inactive until a chemical signal in the cells tells it to become active. In Camurati-Engelmann disease, the TGFB-1 protein is always active. This leads to increased bone density and decreased body fat and muscle tissue, and causes the symptoms of Camurati-Engelmann disease.

Occasionally, individuals with Camurati-Engelmann disease do not have identified mutations in the *TGFB-1* gene, and the cause of the disease is unknown.

Demographics

Camurati-Engelmann disease, which affects men and women equally, is a very rare disease that develops during childhood or young adulthood. It usually develops between ages four and ten, but may affect children as young as three months old. Some individuals may

KEY TERMS

Endosteal—Relating to the endosteum, which is the lining of the medullary cavity.

Intracranial pressure—The pressure of the fluid between the brain and skull.

Medullary cavity—The marrow-filled cavity inside a long bone (such as the femur).

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual and can be transmitted to offspring. The change may manifest itself as a disease.

Periosteal—Relating to the periosteum, which is the connective tissue that covers all human bones.

develop Camurati-Engelmann disease any time before age 30.

Signs and symptoms

The main symptoms of Camurati-Engelmann disease are severe pain in the legs, weak and underdeveloped leg muscles, and a “waddling” walk. Other symptoms include bowed legs, unusually long limbs, spine problems such as scoliosis or lumbar lordosis, and flat feet. People with the disease may complain of headaches, lack of energy or appetite, vision problems, and an aching feeling in their hands and feet and, less often, in the jaw. Infants with Camurati-Engelmann disease may experience feeding problems or a failure to thrive, and have a malnourished appearance.

Camurati-Engelmann disease causes telltale changes in the structure of the femur and tibia around the mid-shaft areas. Certain bone regions (specifically, the endosteal and periosteal surfaces) become abnormally thickened and hardened, which in turn narrows the medullary canal. Camurati-Engelmann disease also causes the long bones to become fusiform, a technical term indicating a tapered, spindle-like shape. In addition to these changes, Camurati-Engelmann disease may cause abnormal hardening of other bones: in the hands and feet, at the base of the skull, and in the jaw. Camurati-Engelmann disease may also involve liver and spleen enlargement, compression of the optic nerves, and increased intracranial pressure.

Diagnosis

Classic symptoms such as severe leg pain, underdeveloped leg muscles, and a waddling gait are often the first indication of the disease. An infant may initially

QUESTIONS TO ASK YOUR DOCTOR

- At what age can Camurati-Engelmann disease be diagnosed, and on what characteristics is that diagnosis made?
- What kinds of medication and/or surgical procedures are used to treat Camurati-Engelmann disease?
- Does this genetic disorder become worse or better over time?
- Could this genetic disorder remain about the same as a child grows older?
- If my spouse and I are planning to have other children, should we consult a genetic counselor for more information about this disease?

experience feeding problems or failure to thrive (though these are more often the result of other problems). Imaging procedures such as a CT scan are used to detect the bone abnormalities associated with the condition, which mainly involve the thickening and sclerosis of the long bones of the legs. In some cases, x-ray studies of the skull are necessary. Blood tests and a biopsy of muscle tissue may be recommended.

In diagnosing Camurati-Engelmann disease, a doctor must distinguish it from other conditions that produce similar symptoms, such as Paget disease and certain types of muscular dystrophy.

Treatment and management

The treatment of Camurati-Engelmann disease focuses on alleviating symptoms. While the changes in bone associated with the condition cannot be reversed, the use of steroid drugs such as cortisone or prednisone can ease bone pain and strengthen muscle. Surgery to repair muscles or bones is rarely necessary. Procedures to repair nerves in the eye are generally considered ineffective.

Prognosis

While Camurati-Engelmann disease does not affect life expectancy, the prognosis for the condition varies. Some people affected by the disease are virtually free of symptoms; others are severely disabled. In some cases, the muscle weakness associated with Camurati-Engelmann disease diminishes or goes away completely with the passage of time. In other people, the effects of

the disease seem to remain the same or slowly worsen during adulthood.

Canavan disease

Definition

Canavan disease, which occurs when the body produces less-than-normal amounts of a protein called aspartoacylase, is a fatal inherited disorder characterized by progressive damage to the brain and nervous system.

Description

Canavan disease is named after Dr. Myrtille Canavan, who described a patient with the symptoms of Canavan disease but mistakenly diagnosed this patient with Schilder's disease. It was not until 1949 that Canavan disease was recognized as a unique genetic disease by Van Bogaert and Bertrand. The credit went to Dr. Canavan,

KEY TERMS

Amniocentesis—A procedure performed at 16-18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid or cells from it can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Amniotic fluid—The fluid that surrounds a developing baby during pregnancy.

Amniotic sac—A sac that contains the fetus, which is surrounded by amniotic fluid.

Biochemical testing—Measuring the amount or activity of a particular enzyme or protein in a sample of blood or urine or other tissue from the body.

Carrier—A person who possesses a gene for an abnormal trait without showing signs of the disorder. The person may pass the abnormal gene on to offspring.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10 to 12 weeks of gestation. Under ultrasound guidance, a needle is inserted either through the mother's vagina or abdominal wall, and a sample of cells is collected from around the early embryo. These cells are then tested for chromosomal abnormalities or other genetic diseases.

Chromosome—A microscopic thread-like structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their

shape and size (structure) may lead to physical or mental abnormalities.

Deoxyribonucleic acid (DNA)—The genetic material in cells that holds the inherited instructions for growth, development, and cellular functioning.

DNA testing—Analysis of DNA (the genetic component of cells) to determine changes in genes that may indicate a specific disorder.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein. It is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Poor muscle tone (hypotonia)—A condition in which infants appear limp at birth and cannot keep their knees and elbows bent.

Prenatal testing—Testing for a disease such as a genetic condition in an unborn baby.

Protein—Important building blocks of the body, composed of amino acids with functions contributing to the formation of body structures and controlling the basic functions of the human body.

White matter—A substance found in the brain and nervous system that protects nerves and allows messages to be sent to and from the brain to the various parts of the body.

however, whose initial description of the disease dominated the medical literature.

Canavan disease, which is also called aspartoacylase deficiency, spongy degeneration of the brain, and infantile spongy degeneration, results from a deficiency of the enzyme aspartoacylase. This deficiency ultimately causes progressive damage to the brain and nervous system, along with intellectual disability, seizures, tremors, muscle weakness, blindness, and an increase in head size. Although most people with Canavan disease die in their teens, some die in childhood, and some live into their 20s and 30s.

Canavan disease is sometimes called spongy degeneration of the brain, because it is characterized by a sponginess or swelling of the brain cells and by a destruction of the white matter of the brain. It is an autosomal

recessive genetic condition that is found in all ethnic groups, but is most common in people of Ashkenazi (Eastern European) Jewish descent.

Genetic profile

Canavan disease is a rare autosomal recessive genetic disease. A person with Canavan disease has changes (mutations) in both of the genes responsible for producing the enzyme aspartoacylase and has inherited one changed gene from his or her mother and one changed gene from his or her father. The aspartoacylase gene is called *ASPA* and is located on chromosome number 17. There are a number of different types of changes in the *ASPA* gene that can cause Canavan disease, although there are three common gene changes. When the *ASPA* gene is altered, it produces reduced levels of

aspartoacylase or none at all. The amount of aspartoacylase produced depends on the type of gene alteration. Reduced production of aspartoacylase leads to lower-than-normal amounts of this enzyme in the brain and nervous system. Aspartoacylase is responsible for breaking down a substance called N-acetylaspartic acid (NAA). When the body produces decreased levels of aspartoacylase, higher levels of NAA build up. This substance destroys the white matter of the brain and nervous system and causes the symptoms of Canavan disease.

Parents who have a child with Canavan disease are called carriers, since they each possess one changed *ASPA* gene and one unchanged *ASPA* gene. Carriers usually do not have any symptoms, since they have one unchanged gene that can produce enough aspartoacylase to prevent the buildup of NAA. Each child born to parents who are both carriers for Canavan disease has a 25% chance of having Canavan disease, a 50% chance of being a carrier, and a 25% chance of being neither a carrier nor affected with Canavan disease.

Demographics

Although Canavan disease is found in people of all ethnicities, it is most common in Ashkenazi Jewish individuals. Approximately one in 40 Ashkenazi Jewish individuals is a carrier for Canavan disease, and approximately one in 6,400 Ashkenazi Jewish people is born with Canavan disease.

Signs and symptoms

Most infants with Canavan disease appear normal for the first month of life. The onset of symptoms, such as a lack of head control and poor muscle tone, usually begins by two to three months of age. Still, some may have an onset of the disease in later childhood. Children with Canavan disease usually experience sleep disturbances, irritability, and swallowing and feeding difficulties after the first or second year of life. In many cases, irritability resolves by the third year. As the child with Canavan disease grows older, there is a deterioration of mental and physical functioning. The speed at which this deterioration occurs will vary for each affected person. Children with Canavan disease have an intellectual disability. Most will never be able to sit, stand, walk, or talk, although they may learn to laugh, smile, and reach for objects. People with Canavan disease have increasing difficulties in controlling their muscles. Initially, those affected have poor muscle tone; eventually their muscles become stiff and difficult to move and may exhibit spasms. Canavan disease can cause vision problems to the point that some people with it may eventually become blind. People with

Canavan disease typically have disproportionately large heads and may experience seizures.

Diagnosis

Diagnostic testing

Canavan disease should be suspected in a person with a large head who has poor muscle control, a lack of head control, and destroyed white matter of the brain. Abnormalities of the brain can be detected through a computed tomography (CT) scan or magnetic resonance imaging (MRI). A diagnosis of Canavan disease can usually be confirmed by measuring the amount of NAA in a urine sample, since a person with Canavan disease typically has five to ten times the normal amount of NAA in their urine. Canavan disease can be less accurately diagnosed by measuring the amount of aspartoacylase enzyme present in a sample of skin cells or by measuring the enzyme from a blood sample.

Once a biochemical diagnosis of Canavan disease is made, DNA testing may be recommended. Detection of an *ASPA* gene alteration in a person with Canavan disease can confirm an uncertain diagnosis and help facilitate prenatal diagnosis and carrier testing of relatives. Testing for the *ASPA* gene is available from certain laboratories. These tests are specifically designed to detect variants of the *ASPA* gene. Two mutations have been identified that make up 98% of the alterations that cause the disease in people of Ashkenazi Jewish descent. Tests search for several genes that can occur among people of Ashkenazi Jewish descent. The tests include the *ASPA* gene.

Carrier testing

DNA testing is the only means of identifying carriers of Canavan disease. If possible, it should be performed on the affected family member first. If a change in the *ASPA* gene is detected, then carrier testing can be performed on relatives such as siblings, with an accuracy of greater than 99%. If the affected relative does not possess a detectable *ASPA* gene change, then carrier testing will be inaccurate and should not be performed. If DNA testing of the affected relative cannot be performed, carrier testing of family members can still be performed but will be less accurate. Carrier testing for the three common *ASPA* gene mutations identifies approximately 97%–99% of Ashkenazi Jewish carriers and 40% to 55% of carriers from other ethnic backgrounds.

Carrier testing of individuals without a family history of Canavan disease is only recommended for people of Ashkenazi Jewish background, since they have a higher risk of being carriers. Both the American College of Obstetricians and Gynecologists and the American College of Medical Genetics have recommended that

DNA testing for Canavan disease be offered to all couples of Eastern European Jewish (Ashkenazi) descent who are planning to have children or who are currently expecting. If only one member of the couple is of Ashkenazi Jewish background, then testing of them should be performed first. If the Jewish partner is a carrier, then testing of the non-Jewish partner is recommended.

Prenatal testing

Prenatal testing through chorionic villus sampling (CVS) and amniocentesis is available to parents who are both carriers for Canavan disease. If both parents possess an *ASPA* gene change, which is identified through DNA testing, then DNA testing of their baby can be performed. Some parents are known to be carriers for Canavan disease, yet they do not possess *ASPA* gene changes that are detectable through DNA testing. Prenatal diagnosis can be performed in those cases by measuring the amount of NAA in the amniotic fluid obtained from an amniocentesis. This type of prenatal testing is less accurate than DNA testing and can lead to misdiagnoses.

Treatment and management

As of 2021, there was no cure for Canavan disease. Therefore, treatment largely involves the management of symptoms. Seizures and irritability can often be controlled through medication. Children with loss of head control will often benefit from the use of modified seats that can provide full head support. When feeding and swallowing become difficult, treatment may involve liquid diets, feeding tubes, or both. Feeding tubes are inserted either through the nose (nasogastric tube) or through a permanent incision in the stomach (gastrostomy). Patients with a later onset and slower progression of the disease may benefit from special-needs education and physical therapy.

A new type of treatment called gene replacement therapy shows promise in helping people with Canavan disease. The goal of gene replacement therapy is to restore normal amounts of aspartoacylase in the brain and nervous system and to prevent the build-up of NAA and the symptoms of Canavan disease. The clinical trials that have delivered the *ASPA* gene encoding the NAA enzyme to the brain have offered promising results.

Clinical trials for Canavan disease including new gene therapies, experimental drug treatments, and procedures are underway. Participation in a U.S. clinical trial is voluntary and cost-free to the participant. All clinical trials receiving U.S. government funding and some supported by private industry are posted at [## **QUESTIONS TO ASK YOUR DOCTOR**](https://www</p>
</div>
<div data-bbox=)

- Please explain the cause or causes of Canavan disease.
- Are there treatments or other forms of care that can be provided to a child born with Canavan disease to extend his or her life?
- Is it possible to predict the lifespan of a child born with Canavan disease, and, if so, on what is that prediction based?
- What types of medical specialists will a child born with Canavan disease need to see?

.clinicaltrials.gov. Foreign trials are posted at <https://www.orpha.net>.

Prognosis

The lifespan and progression of Canavan disease are variable and may be partially dependent on the type of medical care provided and other genetic risk factors. Most people with Canavan disease die before age 10, although some live into their teens or survive their 20s. There can be a high degree of variability, even within families. Some families report having one child die in infancy and another die in adulthood.

Cancer

Definition

Cancer is not just one disease, but a large group of diseases characterized by uncontrolled and malignant growth of some cells in the human body and the ability of these cells to spread to distant sites (metastasis). If the spread is not controlled through surgery, chemotherapy, radiation, or other treatments, cancer can result in death. According to predictions from the American Cancer Society, the most common cause of cancer in males in the United States in 2021 was prostate cancer (26 percent of all male cancers), followed by lung cancer (12 percent). Among females, the most common cause of cancer in 2021 was breast cancer (30 percent), followed by lung cancer (13 percent). In considering deaths from lung cancer for both men and women together, lung cancer was responsible for 22 percent of all cancer deaths in 2021.

Description

Cancer by definition is a disease of the genes, which are formed from deoxyribonucleic acid (DNA) and located on chromosomes. They carry the hereditary instructions for the cell to make the proteins required for many body functions. Proteins are special chemical compounds that mostly contain carbon, hydrogen, oxygen, and nitrogen. Our bodies need them to carry out all of the processes that allow us to breathe, think, move, or do most anything else.

Throughout people's lives, the cells in their bodies are growing, dividing, and replacing themselves. Many genes produce proteins that are involved in controlling the processes of cell growth and division. A change (mutation) occurring in the DNA molecules can disrupt the genes and produce faulty proteins and cells. Abnormal cells can start dividing uncontrollably, eventually forming a new growth known as a "tumor" or "neoplasm"

Colored transmission electron micrograph (TEM) of a cancer cell dividing by mitosis into two new daughter cells. This image was made during the telophase (fourth stage) of mitotic division, when the cell's genetic material (dark blue) has been separated via the spindle (center) into two identical populations. (Steve Gschmeissner/Science Source)

(medical term for cancer meaning "new growth"). In a healthy individual, the immune system can recognize the neoplastic cells and destroy them before they get a chance to divide. However, some abnormal cells may escape immune detection and survive to become cancerous.

Tumors are of two type: benign or malignant. A benign tumor is usually slowly growing and does not spread or invade the surrounding tissue. Once the tumor is removed, it will not usually start growing again. A malignant tumor, on the other hand, invades surrounding tissue and may spread to other parts of the body, often very distant from the location of the first tumor. Malignant tumors often can be surgically removed, but if the cancer cells have spread too much or too far, the cancer becomes very difficult, if not impossible, to treat.

Most cancers are caused by changes in the cell's DNA that result from exposure to a harmful environment. Environmental factors that are responsible for causing the initial mutation in the DNA are called carcinogens. Other factors can cause cancer as well. For example, certain hormones have been shown to have an effect on the growth or control of a particular cell line. Hormones are substances made by one organ and passed through the bloodstream to affect the function of other cells in another organ.

While there is scientific evidence that both environmental and genetic factors play roles in most cancers, only 5%–10% of all cancers are classified as hereditary, which means that a faulty gene that may cause cancer is passed from parent to child. That results in a greater risk for that type of cancer in the offspring of the family.

However, if someone has a cancer-causing gene, they will not necessarily develop cancer. Rather, they are thought to be predisposed to a type of cancer or more likely to get that cancer, compared to the general population. Various cancers are known to have a hereditary component. A few examples are breast cancer, prostate cancer, colon cancer, ovarian cancer, and skin cancer.

Aside from genes, certain physiological traits that are inherited can contribute to cancers as well. For example, fair skin makes a person more likely to develop skin cancer but only if they also have prolonged exposure to intensive sunlight.

According to experts such as Rebecca L. Siegel et al. of the American Cancer Society, the coronavirus disease 2019 (COVID-19) pandemic likely had some effects on cancer, but it will take several years for researchers to assess its effects. For example, because of this pandemic in 2020 and 2021, many routine screenings for cancer were delayed, such as screening for breast cancer (mammograms) or for colorectal cancer (colonoscopies). Some treatments for cancer patients may also have been delayed, affecting patients' prognoses. Future research will provide this information.

There are several different types of cancers. Some of the most common types include:

- **Carcinomas.** These cancers arise in the epithelium (the layers of cells covering the body's surface and lining the internal organs and various glands). About 80% of human cancers fall into this category. Carcinomas can be subdivided into two subtypes: adenocarcinomas and squamous cell carcinomas. Adenocarcinomas are cancers that develop in an organ or a gland, while squamous cell carcinomas refer to cancers that originate in the skin.
- **Melanomas.** These cancers also originate in the skin, usually in the pigment cells (melanocytes).
- **Sarcomas.** These are cancers of the supporting tissues of the body, such as bone, muscle, cartilage, and fat.
- **Leukemias.** Cancers of the blood or blood-forming organs.
- **Lymphomas.** This type affects the lymphatic system, a network of vessels and nodes that acts as a filter in the body. It distributes nutrients to blood and tissue and prevents bacteria and other foreign substances from entering the bloodstream.
- **Gliomas.** Cancers of the nerve tissue.

The most common cancers are skin cancer, lung cancer, colon and rectal (colorectal) cancer, breast cancer (in women), uterine cancer in women, bladder cancer in men, and prostate cancer (in men). In addition, cancers of the kidneys, ovaries, pancreas, thyroid gland, and blood and lymph node cancer (leukemias and lymphomas) are included among the major cancers that affect most Americans.

Colored scanning electron micrograph of cancer cells (green). Two lymphocyte blood cells (yellow) are also pictured. (Stem Jems/Science Source)

Genetic profile

Three classes of genes are believed to play roles in the development of cancer:

- **Proto-oncogenes.** These genes encourage and promote the normal growth and division of cells. When they are defective, they become oncogenes, which are overactive proto-oncogenes that cause excessive cell multiplication that can lead to tumors.
- **Tumor suppressor genes.** These genes act as brakes on cell growth. They prevent cells from multiplying uncontrollably. If these genes are defective, there is no control over cell growth and tumors can result. According to the American Cancer Society, most family cancer syndromes are caused by inherited defects in the tumor suppressor genes.
- **DNA repair genes.** These genes ensure that each strand of DNA is correctly copied during cell division. When these genes do not function properly, the replicated DNA is likely to have mistakes. These errors lead to defects in other genes and can also lead to tumor formation.

Childhood cancers associated with congenital syndromes or malformations

Syndrome or Anomaly	Tumor
Aniridia	Wilms tumor
Hemihypertrophy	Wilms tumor, hepatoblastoma, adrenocortical carcinoma
Genito-urinary abnormalities (including testicle maldescent) Beckwith-Wiedemann syndrome	Wilms tumor, Ewing sarcoma, nephroblastoma, testicular carcinoma Wilms tumor, neuroblastoma, adrenocortical carcinoma
Dysplastic naevus syndrome	Melanoma
Nevoid basal cell carcinoma syndrome	Basal cell carcinoma, medulloblastoma, rhabdomyosarcoma Leukemia
Poland syndrome	Leukemia, retinoblastoma
Trisomy-21 (Down syndrome)	Leukemia, gastrointestinal carcinoma
Bloom syndrome	EBV-associated B-lymphocyte lymphoma/leukemia EBV-associated B-lymphocyte lymphoma
Severe combined immune deficiency disease Wiscott-Aldridge syndrome	EBV-associated B-lymphocyte lymphoma, gastric carcinoma Wilms tumor, osteosarcoma, Ewing sarcoma
Ataxia telangiectasia Retinoblastoma Fanconi anemia	Leukemia, squamous cell carcinoma
Multiple endocrine neoplasia syndromes (MEN I, II, III)	Adenomas of islet cells, pituitary, parathyroids, and adrenal glands Submucosal neuromas of the tongue, lips, eyelids Pheochromocytomas, medullary carcinoma of the thyroid, malignant schwannoma, non-appendiceal carcinoid
Neurofibromatosis (von Recklinghausen syndrome)	Rhabdomyosarcoma, fibrosarcoma, pheochromocytomas, opticglioma, meningioma

Childhood cancers associated with congenital syndromes or malformations (Gale)

As stated, approximately 5% to 10% of cancers have a hereditary component. In those cancers, children do not inherit cancer from their parents. Rather, they inherit a predisposition to cancer. For example, a child may inherit a faulty tumor suppressor gene from one parent. This gene is not able to control cell growth, but the corresponding gene inherited from the other parent may still be functional. Cell growth is then under control. However, as this child grows up, radiation, pollution, or any other harmful environmental factor could change (mutate) the previously healthy gene, making it abnormal as well. However, if a child inherits mutated tumor suppressor genes from both parents, a tumor is most likely to develop. Defects in proto-oncogenes and DNA repair genes can be inherited as well, leaving a person more vulnerable to cancer than other individuals.

Additionally, some cancers seem to be familial. In those cancers, there is not a specific gene that is responsible for the clustering of cancer in a family. However, a particular type of cancer may be seen more often than expected, which may be due to a combination of genetic and environmental factors.

Demographics

Cancer is the second leading cause of death in the United States, surpassed only by heart disease. Nearly 1.9 million new cases of cancer will be diagnosed in 2021, as predicted by the American Cancer Society. In addition,

there will be an estimated 608,570 cancer deaths in 2021, or more than 1,600 deaths per day. Some people diagnosed with cancer in 2021 will be cured of their cancer, while others will remain affected with the disease and undergoing treatment. Many patients will die of their cancer.

Anyone is potentially at risk for developing cancer. Since the occurrence of cancer increases as a person ages, most of the cases are seen in adults who are middle-aged or older. Nearly 80% of cancers are diagnosed in people who are 55 years of age and older.

Lifetime risk is the term that cancer researchers use to refer to the probability that an individual will develop cancer over the course of their lifetime. In the United States, men have a one-in-two lifetime risk of developing cancer, and for women the risk is one in three. Overall, African Americans are more likely to develop cancer than Caucasians, and they are also 33% more likely to die of cancer than Caucasians. Racial disparity is even greater for American Indian/Alaska Natives with cancer, who have a 51% higher risk for death from cancer than do Caucasian individuals with cancer.

The major risk factors for cancer are: tobacco, alcohol, diet, sexual and reproductive behavior, infectious agents, family history, occupation, environment, and pollution.

Tobacco

Smoking continues to be the leading preventable cause of cancer, while lung cancer itself is the leading cause of

cancer deaths in both men and women. About 82 percent of the lung cancer cases occur in smokers, yet researchers have discovered that individuals who end their smoking habit by age 40 reduce their risk of smoking-related disease by an estimated 90 percent. There are many medications and treatments to help people stop smoking. Smoking has also been shown to be a contributory factor in cancers of the mouth, pharynx, larynx, esophagus, pancreas, uterine cervix, kidney, and bladder. Scientists have also shown that secondhand smoke (or passive smoking) increases one's risk of developing cancer.

Alcohol

Excessive consumption of alcohol is a risk factor in some cancers, such as liver cancer and breast cancer. Alcohol in combination with tobacco significantly increases the chances that an individual will develop mouth, pharynx, larynx, and esophageal cancers. The combined effect of tobacco and alcohol is greater than the sum of their individual effects.

Diet and physical activity

One-third of all cancer deaths are due to a poor adult diet. High-fat diets have been associated with cancers of the colon and rectum, prostate, endometrium, and possibly breast. Consumption of meat, especially red meat, has been associated with increased cancer at various sites, such as the colon and prostate. Additionally, a high-calorie diet and low level of physical activity can lead to obesity, which increases the risk for cancer at various sites, including the breast, colon and rectum, prostate, kidney, and endometrium.

Sexual and reproductive behavior

The human papilloma virus (HPV), which is a sexually transmitted pathogen, has been shown to cause cancer of the female cervix and oropharyngeal cancer in men who have oral sex with infected partners. Having many sexual partners and becoming sexually active early in life has been shown to increase a woman's chances of contracting this disease and, therefore, developing cervical cancer. In addition, it has also been shown that women who do not bear any children or those who become pregnant late in life have an increased risk for both ovarian and breast cancer. A vaccine against HPV is available to adolescents and young adults up to age 26 years. This vaccine protects individuals as well as their future sex partners from HPV.

Hormone replacement therapy

As women go through menopause, some doctors may recommend hormone replacement therapy (HRT). HRT involves taking female hormones (estrogen and

progesterone) to control certain symptoms that occur during that time of a woman's life, such as hot flashes and vaginal dryness. According to the nonprofit advocacy group breastcancer.org, located in Ardmore, Pennsylvania, taking combination therapy (both progesterone and estrogen) increases the risk for breast cancer by about 75%, especially in the first few years of taking this form of hormone replacement therapy. In contrast, taking estrogen therapy alone also elevates the risk for breast cancer, but the risk occurs after about a decade of taking estrogen replacement therapy (ERT). However, ERT may also increase a woman's risk for ovarian cancer. Taking estrogen alone also may increase the risk for uterine cancer. As a result, menopausal women should only consider any form of HRT after a very careful consultation with a physician as well as considering the personal possible risk factors for breast cancer, such as a family history of the disease.

Family history

Some types of cancers tend to occur more frequently among members of a family. In most cases, this happens either by chance or due to common family habits such as cigarette smoking, excessive eating causing obesity, or excessive sun exposure. However, familial cancer can also be due to a genetic predisposition that is passed from generation to generation. For example, if a certain gene called *BRCA1* or *BRCA2* is defective in a given family, members of that family may have an increased risk to develop breast, colon, ovarian, and prostate cancer. Other defective genes have been identified that can make a person susceptible to various types of cancer. Therefore, inheriting particular genes can increase a person's chance to develop cancer.

Occupational hazards

There is strong evidence proving that occupational hazards account for 4% of all cancer deaths. For example, asbestos workers have an increased incidence of lung cancer. Similarly, bladder cancer is associated with dye, rubber, and gas workers; skin and lung cancer with smelters, gold miners, and arsenic workers; leukemia with glue and varnish workers; liver cancer with PVC manufacturers; and lung, bone, and bone marrow cancer with radiologists and uranium miners.

Environment

High-frequency radiation has been shown to cause cancer. Ultraviolet radiation from the sun accounts for a majority of melanomas. Other sources of radiation are x-rays, radioactive substances, and rays that enter the Earth's atmosphere from outer space. Virtually any part of the body can be affected by these types of radiation, especially the bone marrow and the thyroid gland.

Being exposed to substances such as certain chemicals, metals, or pesticides can increase the risk of cancer. Asbestos is an example of a well-known carcinogen. It increases the risk for lung cancer. This risk is increased even further for a smoker who is exposed to asbestos over a period of time.

Signs and symptoms

Almost every tissue of the body can give rise to abnormal cells that cause cancer, and each of these cancers is very different in symptoms and prognosis.

Cancer is also a progressive disease and goes through several stages. Each stage can produce a number of symptoms. Unfortunately, many types of cancer do not display any obvious symptoms or cause pain until the disease has progressed to an advanced stage. Early signs of cancer are often subtle and are easily mistaken for signs of other less dangerous diseases. However, if cancer is diagnosed in its early stages, the prognosis is much improved compared to when diagnosis occurs at an advanced stage.

Despite the fact that there are several hundred different types of cancers producing very different symptoms, the American Cancer Society (ACS) has established the following seven symptoms as possible warning signs of cancer:

- changes in the size, color, or shape of a wart or a mole
- a sore that does not heal
- persistent cough, hoarseness, or sore throat
- a lump or thickening in the breast or elsewhere
- unusual bleeding or discharge
- chronic indigestion or difficulty in swallowing
- any change in bowel or bladder habits

Many other diseases can produce similar symptoms. However, it is important to have these symptoms checked as soon as possible, especially if they do not stop. The earlier a cancer is diagnosed and treated, the better the chance of a successful treatment. Many cancers, such as breast cancer, might not have any early symptoms. Therefore, it is important to undergo routine screening tests, such as mammograms.

Diagnosis

If a person has symptoms of cancer, the doctor will begin with a complete medical history and a thorough physical examination. Different parts of the body will be examined to identify any variations from the normal size, feel, and texture of the organ or tissue. The doctor may order various other tests as well.

Laboratory tests of blood and urine are often used to obtain information about a person's health. If cancer is suspected, a special test can be done that measures the amount of certain substances called tumor markers in the blood, urine, or particular tissues. These proteins are released from some types of cancer cells. Thus, the levels of these substances may be abnormal when certain cancers are present. However, laboratory tests alone cannot be used to make a definitive diagnosis of cancer. Blood tests are generally more useful in monitoring the effectiveness of the treatment or in following the course of the disease and detecting any signs of recurrence.

A doctor may also look for tumors by examining pictures of areas inside the body. The most common way to obtain these images is by using x-rays or imaging scans to obtain pictures of the inside of the body, such as computed tomography scanning (CT scan), magnetic resonance imaging (MRI), positron emission tomography (PET), or ultrasonography.

The most definitive diagnostic test is the biopsy. In this technique, a piece of tissue from the suspected cancerous tumor is surgically removed for examination under a microscope. A biopsy provides information about the cellular nature of the abnormality, the stage it has reached, the aggressiveness of the cancer, and the extent of its spread. Further analysis of the tissue defines the cause of the abnormality. Since a biopsy provides the most accurate analysis, it is considered the gold standard of diagnostic tests for cancer.

Regular screening examinations conducted by healthcare professionals can result in the early detection of various types of cancer. If detected at an early stage, treatment is more likely to be successful. For example, the American Cancer Society recommends an annual mammogram (x-ray of the breast) for women aged 45 to 54 years to screen for breast cancer. If a woman wishes to start breast cancer screening between the ages of 40 and 44, this option should be extended to her. Women who are age 55 and older may have annual screening or screening every two years, for as long as the woman is anticipated to live at least ten more years. The American Cancer Society also recommends either stool tests or a colonoscopy or sigmoidoscopy to detect cancer or a risk for cancer in the colon, starting at age 45. A colonoscopy is a procedure in which a thin lighted tube is rectally inserted so that the doctor may view the inside of the entire colon. If the doctor detects any precancerous polyps, they will be removed during the procedure. A sigmoidoscopy is another procedure, but it does not examine the entire colon. Stool-based tests include the fecal immunochemical test (FIT), which checks for blood in the stool. Patients can perform this test in their own home. A guaiac-based fecal occult blood test (gFOBT) is another

KEY TERMS

Adenocarcinoma—A type of cancer that originates in glandular tissue, has a glandular form, or both.

Adenomatous—Derived from glandular structures.

Aflatoxin—A substance produced by molds that grow on rice and peanuts. Exposure to aflatoxin is thought to explain the high rates of primary liver cancer in Africa and parts of Asia.

Alpha-fetoprotein (AFP)—A chemical substance produced by the fetus and found in the fetal circulation. AFP is also found in abnormally high concentrations in most patients with primary liver cancer.

Alteration—Change or mutation in a gene, specifically in the DNA that codes for the gene.

Anti-androgen drugs—Drugs that block the activity of the male hormone.

Astrocytoma—Tumor of the central nervous system derived from astrocytes.

Barium—A chemical swallowed to help with outlining the gastrointestinal system during an x-ray study.

Benign—Referring to a noncancerous tumor that does not spread and is not life-threatening.

Benign prostatic hyperplasia (BPH)—A noncancerous condition of the prostate that causes growth of the prostate tissue, thus enlarging the prostate and blocking urination.

Bilateral breast cancer—Cancer of both breasts, caused by two separate cancer processes.

Bile—A substance produced by the liver and concentrated and stored in the gallbladder. Bile contains a number of different substances, including bile salts, cholesterol, and bilirubin.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Bone marrow—A spongy tissue located in the hollow centers of certain bones, particularly the bones of the central skeleton. Bone marrow is the site of blood cell generation.

BRCA2—A gene, when altered, that is known to cause increased risks of breast, ovarian, and possibly pancreatic cancer.

Breast biopsy—A small sample of tissue taken from the breast and studied, to diagnose and determine the exact type of breast cancer.

Breast self-exam (BSE)—Examination by an individual of their own breasts.

CA-125 (Carbohydrate antigen 125)—A protein that is sometimes high when ovarian cancer is present. A blood sample can determine the level of CA-125 present.

Cancer—A disease caused by uncontrolled growth of the body's cells.

Carcinogen—Any substance capable of causing cancer by damaging a cell's genome.

Cationic trypsinogen gene—A gene known to cause hereditary pancreatitis when significantly altered.

CDH1—A gene involved in cell-to-cell connection. Alterations in this gene have been found in several families with increased rates of gastric cancer.

CDKN2A—Gene, when altered, known to cause Familial Atypical Multiple Mole Melanoma (FAMMM) syndrome and possibly increased pancreatic cancer risk.

Central nervous system—In humans, the brain, the cranial nerves, and the spinal cord. It is responsible for the coordination and control of all bodily activities.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing them.

type of stool test that patients may perform at home. The stool DNA test is a third type of stool test; it checks for abnormal DNA cells as well as for hidden blood. In the United States, only the Cologuard test is approved to test for both blood in the stool and DNA changes. If a stool-based test is positive, a doctor may choose to perform a colonoscopy. Patients should check with their physicians to determine the needed frequency of these tests. Self-examinations for cancers of the breast, testes, mouth, and skin can also help in detecting tumors.

Recent progress in molecular biology and cancer genetics have led to the development of several tests designed to assess one's risk of developing certain types of cancer. This genetic testing involves looking closely at genes that have been linked to particular cancers. If these genes are abnormal, a person's risk for certain types of cancer increases. At present, there are many limitations to genetic testing. The tests may be uninformative, and they are useful to a very small number of people. There are also concerns about insurance

KEY TERMS (continued)

Chronic atrophic gastritis—Irritation and breakdown of the stomach wall over a period of time.

Cirrhosis—A chronic degenerative disease of the liver in which normal cells are replaced by fibrous tissue. Cirrhosis is a major risk factor for the later development of liver cancer.

Clinical breast exam (CBE)—Examination of the breasts, performed by a physician or nurse.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Desmoid tumor—A benign, firm mass of scar-like connective tissue.

Distal—Away from the point of origin.

Dominant inheritance—A type of genetic inheritance pattern that results in one form of a gene being dominant over other forms. Therefore, the dominant allele can express itself and cause disease, even if only one copy is present.

Duct—A tube-like structure that carries secretions from glands.

Duodenum—The portion of the small intestine nearest the stomach; the first of three parts of the small intestine.

Endoscope—A slender, tubular optical instrument used as a viewing system for examining an inner part of the body and, with an attached instrument, for biopsy or surgery.

Endoscopic retrograde cholangiopancreatography (ERCP)—A method of viewing the pancreas by inserting a thin tube down the throat into the pancreatic and bile ducts, injecting dye, and performing x-rays.

Ependymoma—A tumor of the central nervous system derived from cells that line the central canal of the spinal cord and the ventricles of the brain.

Epidermoid cyst—A benign cystic tumor derived from epithelial cells.

Epithelium—The layer of cells that cover the open surfaces of the body, such as the skin and mucous membranes.

Esophagus—The part of the digestive tract that connects the mouth and stomach; the food pipe.

Estrogen—A female sex hormone.

Exocrine pancreas—The part of the pancreas that secretes digestive enzymes.

Familial adenomatous polyposis (FAP)—An inherited syndrome causing large numbers of polyps and increased risk of colon cancer and other cancers.

Familial gastric cancer—Gastric cancer that occurs at a higher rate in some families.

Fecal occult blood test—A laboratory test of a stool (feces) sample done to identify loss of blood in the gastrointestinal system.

Fine needle aspiration (FNA)—Insertion of a thin needle through the skin to an area of sample tissue.

Gastric—Associated with the stomach.

Gastrointestinal (GI) system—The body system involved in digestion, the breaking down and use of food.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Genetic counselor—A health professional with advanced training in genetics and psychology who educates people about genetic conditions and testing.

Glioblastoma multiforme—A tumor of the central nervous system consisting of undifferentiated glial cells.

coverage and employment discrimination for someone who has an increased risk for cancer. A hereditary cancer clinic can help to assess who may benefit from this type of testing.

Treatment and management

The aim of cancer treatment is to remove all or as much of the tumor as possible and to prevent the metastasis of the primary tumor. While devising a treatment plan

for cancer, the likelihood of curing the cancer must be weighed against the side effects of the treatment. For example, if the cancer is very aggressive and a cure is not possible, then the treatment should be aimed at relieving the symptoms and controlling the cancer for as long as possible.

Cancer treatment can take many different forms, and it is always tailored to the individual patient. The decision on which type of treatment to use depends on the type and

KEY TERMS (continued)

***Helicobacter pylori* (H. pylori)**—A bacterium that infects humans and may be associated with an increased risk of gastric cancer.

Hepatitis—A viral disease characterized by inflammation of the liver cells (hepatocytes). People who are infected with hepatitis B or hepatitis C virus are at an increased risk for developing liver cancer.

Hereditary non-polyposis colon cancer (HNPCC)—A genetic syndrome causing increased cancer risks, most notably colon cancer. Also called Lynch syndrome.

Hormone therapy—Treatment of cancer by changing the hormonal environment, such as by administering testosterone and estrogen.

Immunotherapy—Treatment of cancer by stimulating the body's immune defense system.

Insulin—A hormone produced by the pancreas that is secreted into the bloodstream and regulates blood sugar levels.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Laparoscopy—A diagnostic procedure in which a small incision is made in the abdomen, and a slender, hollow, lighted instrument is passed through it.

Laparotomy—An operation in which the abdominal cavity is opened up through incisions in the abdominal wall.

Li-Fraumeni syndrome—Inherited syndrome known to cause increased risk of different cancers, most notably sarcomas.

Lymph node—A bean-sized mass of tissue that is part of the immune system and is found in different areas of the body.

Magnetic resonance imaging (MRI)—A technique that employs magnetic fields and radio waves to

create detailed images of internal body structures and organs, including the brain.

Malignant—Referring to a tumor growth that spreads to another part of the body, usually cancerous.

Mammogram—A procedure in which both breasts are compressed (or flattened) and exposed to low doses of x-rays, in an attempt to visualize the inner breast tissue.

Medulloblastoma—Tumor of the central nervous system derived from undifferentiated cells of the primitive medullary tube.

Melanoma—A type of skin cancer that develops from melanocytes, the pigment-producing cells in the skin.

Metachronous—Referring to tumors of a similar type that are discovered at different times within the body.

Metastasis—The spreading of cancer from the original site to other locations in the body.

Metastatic cancer—A cancer that has spread to an organ or tissue from a primary cancer located elsewhere in the body.

Multifocal breast cancer—Multiple primary cancers in the same breast.

Mutation—A permanent change in the genetic material; it may alter a trait or characteristic of an individual or manifest as disease, and it can be transmitted to offspring.

Nitrates/nitrites—Chemical compounds found in certain foods and water that, when consumed, may increase the risk of gastric cancer.

Osteoma—A benign bone tumor.

Palliative—Referring to treatment given for relief of symptoms rather than a cure.

location of cancer and the extent to which it has already spread. The doctor will also consider the patient's age, sex, general health status, and personal treatment preferences. Treatment can be local, meaning that it seeks to destroy cancer cells in the tumor and the surrounding area. It can also be systemic, meaning that the treatment drugs will travel through the bloodstream and reach cancer cells all over the body. Surgery and radiation are local treatments. Chemotherapy, immunotherapy, and hormone therapy are examples of systemic treatments.

Surgery

Surgery can be used for many purposes in cancer therapy.

- **Treatment surgery:** This involves removal of the tumor to cure the disease. It is typically performed when the cancer is localized to a discrete area. Along with the cancer, some of the surrounding tissue may also be removed to ensure that no cancer cells remain in the area. Since cancer usually spreads via the lymphatic system,

KEY TERMS (continued)

Pancreas—An organ located in the abdomen that secretes pancreatic juices for digestion and hormones for maintaining blood sugar levels.

Pancreatitis—Inflammation of the pancreas.

Pelvic examination—A physical examination performed by a physician, often associated with a Pap smear. The physician inserts his or her finger into a woman's vagina, attempting to feel the ovaries directly.

Pernicious anemia—A blood condition with decreased numbers of red blood cells related to poor vitamin B12 absorption.

Peutz-Jeghers syndrome (PJS)—An inherited syndrome causing polyps in the digestive tract and spots on the mouth as well as increased risk of cancer.

Polyp—A mass of tissue bulging out from the normal surface of a mucous membrane.

Primary cancer—The first or original cancer site before any metastasis.

Prophylactic—Referring to a procedure or medication given to prevent disease.

Prostatectomy—The surgical removal of the prostate gland.

Proximal—Near the point of origin.

Radiation—High-energy rays used in cancer treatment to kill or shrink cancer cells.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Rectum—The lowermost portion of the intestine that leads to the anus.

Semen—A whitish, opaque fluid that is released at ejaculation and contains sperm.

Seminal vesicles—The pouches above the prostate that store semen.

Sore—An open wound or a bruise or lesion on the skin.

Staging—A method of describing the degree and location of cancer.

Stomach—The muscular hollow organ that secretes enzymes and gastric acid to aid in the digestion of food.

Synchronous—Occurring or existing at the same time.

Testicles—Two egg-shaped glands that produce sperm and male sex hormones.

Testosterone—Hormone produced in the testicles that is involved in male secondary sex characteristics.

Transrectal ultrasound—A procedure where a probe is placed in the rectum. High-frequency sound waves are sent out from the probe and reflected by the prostate. These sound waves produce a pattern of echoes that are then used by the computer to create sonograms or pictures of structures inside the body.

Transvaginal ultrasound—A way to view the ovaries by using sound waves. A probe is inserted into the vagina, and the ovaries can be seen. Color doppler imaging measures the amount of blood flow, as tumors sometimes have high levels of blood flow.

Tumor—An abnormal growth of cells. A tumor may be benign (noncancerous) or malignant (cancerous).

Ultrasound—An imaging technique that uses sound waves to help visualize internal structures in the body.

Whipple procedure—Surgical removal of the pancreas and surrounding areas, including a portion of the small intestine, the duodenum.

X-ray—A high-energy form of electromagnetic radiation. X-rays are used to treat as well as diagnose cancer.

lymph nodes that are near the tumor site may be examined and removed as well.

- **Preventive surgery:** Preventive or prophylactic surgery involves removal of an abnormal area that is likely to become malignant over time. For example, people with a colon disease called ulcerative colitis have an elevated risk of dying from colon cancer. Rather than live with the fear of developing colon cancer, some people may choose to have their colons removed in order to reduce their risk of cancer.

- **Diagnostic purposes:** The most definitive tool for diagnosing cancer is a biopsy. Sometimes a biopsy can be performed by inserting a needle through the skin. In other cases, the only way to obtain a tissue sample for a biopsy is by performing a surgical operation.
- **Cytoreductive surgery:** This is a procedure in which the doctor removes as much of the cancer as possible. He or she then treats the remaining cancer cells with radiation therapy, chemotherapy, or both.

- **Palliative surgery:** This type of surgery is aimed at relieving cancer symptoms or slowing the progression of disease. It is not designed to cure the cancer. For example, if the tumor is very large or has spread to many places in the body, removing the entire tumor may not be an option. However, by decreasing the size of the tumor, pain may be alleviated. This is known as debulking surgery.

Radiation therapy

Radiation therapy uses high-energy rays to kill cancer cells. This treatment may be used instead of surgery. It also may be used before surgery to shrink a tumor, or after surgery to destroy any remaining cancer cells.

Radiation can be either external or internal. In the external form, the radiation comes from a machine that aims the rays at the tumor. In internal radiation (also known as brachytherapy), radioactive material is sealed in needles, seeds, or wires and placed directly in or near the tumor. Radiation may lead to various side effects, such as fatigue, hair loss, and a susceptibility to infections. However, these side effects can usually be controlled.

Chemotherapy

Chemotherapy is the use of drugs to kill cancer cells. The anticancer drugs are usually released into the entire body (systemic therapy) so as to destroy the hard-to-detect cancer cells that have spread and are circulating in the body. Chemotherapy is based on the principle that cancer cells are affected more severely than the normal cells because they are rapidly dividing. Chemotherapeutic drugs can be injected into a vein, the muscle, or the skin, or they may be taken by mouth.

When chemotherapy is used before surgery, it is known as primary chemotherapy or neoadjuvant chemotherapy. Its purpose is usually to reduce the size of the tumor. The more common use of chemotherapy is in adjuvant therapy. In this form of treatment, chemotherapy is given after surgery to destroy any remaining cancer cells and to help prevent cancer from recurring. Chemotherapy can also be used in conjunction with radiation therapy.

The side effects of chemotherapy vary but can include susceptibility to infections, fatigue, poor appetite, weight loss, nausea, diarrhea, and hair loss. Decreased fertility can be a long-term side effect in some patients who undergo chemotherapy.

Bone marrow failure is a complication of chemotherapy. When high-dose chemotherapy is used, this failure is anticipated. Bone marrow transplantation (BMT) or peripheral stem cell transplantation (PSCT) are techniques used to treat this complication. Both techniques provide healthy stem cells for the patient. Stem cells are

QUESTIONS TO ASK YOUR DOCTOR

- What type of cancer do I have?
- What is the stage of my cancer?
- What types of treatments are available for the kind of cancer I have?
- What side effects are associated with each treatment that might be used for my cancer?

immature cells that mature into blood cells. They can replace the patient's own stem cells that have been damaged or destroyed by chemotherapy or radiation. The process allows a patient to undergo very aggressive treatment for their cancer. Patients who receive BMT or PSCT have an increased risk of infection, bleeding, and other side effects due to the chemotherapy and radiation. Graft-versus-host disease may occur as well. This complication occurs when the donated marrow reacts against a patient's tissues. It can occur any time after the transplant. Drugs may be given to reduce the risk of graft-versus-host disease and to treat the problem if it occurs.

Immunotherapy

Immunotherapy, also called biological therapy, is the use of treatments that promote or support the body's immune system response to cancer. The side effects of this immunotherapy are variable but include flu-like symptoms, weakness, loss of appetite, and skin rash. These symptoms will subside after the treatment is completed.

Hormone therapy

Hormone therapy is used to fight certain cancers that depend on hormones for their growth. Drugs can be used to block the production of hormones or change the way they work. Organs that produce hormones may be removed as well. As a result of this therapy, the growth of the tumor slows, and survival may be extended for several months or years.

Alternative and complementary therapies

There are certain cancer therapies that have not been scientifically tested and approved. If these unproven treatments are used instead of the standard therapy, they are known as alternative therapy. If used along with standard therapy, they are known as complementary therapy. The use of alternative therapies must be carefully considered, because some of these unproven treatments

may have life-threatening side effects. If someone uses alternative therapy, they may lose the opportunity to benefit from the standard, proven therapy. However, some complementary therapies may help to relieve symptoms of cancer, decrease the magnitude of side effects from treatment, or improve a patient's sense of well-being. The American Cancer Society recommends that anyone who is considering alternative or complementary therapy consult a healthcare team.

Prevention

According to experts from leading universities in the United States, a person can reduce the chances of getting cancer by following these guidelines:

- eating plenty of fruits and vegetables
- exercising vigorously for at least 20 minutes every day
- avoiding excessive weight gain
- avoiding tobacco (including second hand smoke)
- decreasing or avoiding consumption of animal fats and red meats
- avoiding excessive amounts of alcohol
- avoiding the midday sun (between 11 a.m. and 3 p.m.), when the sun's rays are the strongest
- avoiding risky sexual practices
- avoiding known carcinogens in the environment or workplace

Certain drugs that are currently being used for treatment can also be suitable for prevention. For example, the drug tamoxifen, also called Nolvadex (a pill) or Soltamox (a liquid), has been very effective against breast cancer and is thought to be helpful in the prevention of breast cancer. As with all medications, the drug comes with side effects, which, according to the Cleveland Clinic, may include weight gain, leg swelling, fatigue, menopause-like symptoms (such as night sweats or hot flashes), fatigue, skin rash, and other possible side effects. The doctor should explain these potential side effects to the patient.

Prognosis

Most cancers are curable if detected and treated at their early stages. A cancer patient's prognosis is affected by many factors, particularly the type of cancer the patient has, the stage of the cancer, the extent to which it has metastasized, and the aggressiveness of the cancer. In addition, the patient's age and general health status and the effectiveness of the treatment being pursued are important factors.

To help predict the future outcome of cancer and the likelihood of recovery from the disease, five-year survival rates are used. Five-year survival rates vary widely

for different types of cancers. Suggest using statistics from the NCI's Annual Report to the Nation 2021: Overall Cancer Statistics, which can be found at https://seer.cancer.gov/report_to_nation/statistics.html. The web page includes some graphs that might be reproducible in GEGD. These people may be free of cancer, or they may be undergoing treatment. It is important to note that while this statistic can give some information about the average survival of cancer patients in a given population, it cannot be used to predict individual prognosis. No two patients are exactly alike. For example, the five-year survival rate does not account for differences in detection methods, types of treatments, additional illnesses, and behaviors.

Cancer genetics

Definition

Cancer genetics is the analysis of the multiple alterations in genetic material that transform normal cells into cancer cells. The cancer cells undergo uncontrolled division and proliferation to form tumors and metastasize (spread) to other parts of the body. The study of cancer genetics includes inherited gene mutations or versions of genes (alleles) that increase the risk of cells turning cancerous.

Description

Cancer is considered a genetic disease, or one caused by changes to genes that control how cells function. Spontaneous gene mutations occur frequently in cells throughout the body. In most cases, the cellular machinery either repairs the mutation or signals the cell to die through a process called apoptosis. However, occasionally certain “gatekeeper” mutations or genetic alterations escape these protections, as well as immune-system surveillance.

Most cancers originate from a series of two to eight significant genetic alterations that occur in a single cell over a period of 20 to 30 years. Each of these alterations increases the probability that the cell will grow and divide and transform into a cancer cell rather than die. Most of these mutations are not inherited from parents and are not passed on to offspring. Rather, they occur in somatic (non-germline) cells throughout a person’s lifetime. Even when people inherit genes that increase their susceptibility to certain types of cancer, environmental influences and lifestyle choices, such as smoking, interact with the genes to increase cancer risk.

A cell is more likely to become cancerous if a mutation or other change affects certain types of genes. These types include genes that normally control cell division and proliferation, genes involved in DNA repair, or genes that normally cause the induction of apoptosis in case of genetic damage. Such cancer-promoting genetic alterations most often result from point mutations that change

Illustration of the stages involved in CAR (chimeric antigen receptor) T cell immunotherapy, a process that is being developed to treat cancer. The sequence runs from top left to center right to lower left. The first stage (upper left) involves taking T cells (blue; a type of white blood cell) from the patient. These are then treated (upper right) with a virus (red) that transfers DNA (deoxyribonucleic acid, helical) to the T cells (a form of genetic engineering) that results in the production of chimeric antigen receptor (CAR) proteins. These proteins will be specific to the patient’s cancer. These modified T cells are then grown in the laboratory (Petri dish at lower right) and used to treat the patient (lower left). The technique is known as adoptive cell transfer (ACT). (Gunilla Elam/Science Source)

the DNA sequence of a gene. Other changes may be gene deletions or inversions (reversing the direction of the DNA sequence) or gene amplifications (the creation of multiple copies of a gene). The latter often arise from chromosome rearrangements, such as translocations that move portions of chromosomes to other chromosomes. Epigenetic changes that affect the expression of genes without changing their DNA sequence also are often involved in carcinogenesis, although these effects are not fully understood as of 2021.

Point mutations

DNA is a linear sequence of nucleotides. Each nucleotide is composed of phosphate, deoxyribose (a

Chromosomes and cancer

Cancer type	Associated gene mutation
Chronic myelocytic leukemia	translocation resulting in the Philadelphia chromosome (Ph ¹)
Burkitt's lymphoma	translocation involving the <i>c-myc</i> proto-oncogene
Retinoblastoma	mutation in chromosome 13; mutation can be inherited
Wilms' tumor	mutation in chromosome 11; mutation can be inherited
Colon cancer (occurs sporadically, but also occurs as a familial cancer syndrome)	mutation in adenomatous polyposis coli (APC) gene followed by further mutations
Breast cancer (occurs sporadically and also as a familial cancer syndrome)	mutation affecting the gene <i>BRCA1</i> , or mutation in <i>BRCA2</i>

Cancer genetics (Gale)

sugar), and one of four bases: adenine (A), guanine (G), cytosine (C), or thymine (T). These bases are paired (e.g., A-T and C-G) and form the “rungs” of the double helical structure of DNA. The order of the bases is the genetic code for producing specific proteins. The code for an amino acid in the protein (for example, glutamine-leucine-proline) is expressed as an order of each set of three bases (CAG-CTA-CCA). A point mutation is a single nucleotide change in the DNA sequence changing one or more amino acids in the protein. A point mutation in the thymine base of the second triplet in the sequence would produce CAG-CAA-CCA or glutamine-glutamine-proline in the protein. This mutation may alter the function or activity of the protein.

Chromosomal alterations

Whereas the rate of single-point mutations in cancer cells is similar to that in normal cells, rearrangements in chromosomes occur at a much higher rate in cancer cells and can affect multiple genes. Most solid tumors have numerous chromosome deletions, inversions, translocations, and duplications or other changes in the number of chromosomes. These large-scale alterations can make it difficult to identify the affected genes. However, chromosome translocations sometimes fuse together two genes to create a cancer gene called an oncogene, such as the *BCR-ABL* fusion gene in chronic myelogenous leukemia (CML). Occasionally, translocations inactivate a tumor-suppressor gene. Chromosome deletions can remove a tumor-suppressor gene.

Chromosome rearrangements can also cause gene amplifications, which are very common in human cancers. Gene amplifications producing 10 to 100 copies of a gene may lead to excessive amounts of a protein that can promote cancer cell proliferation.

Cancer genes

Proto-oncogenes, which are normal genes that can undergo mutations to become oncogenes that can turn a cell cancerous, were first discovered in the 1970s. Other classes of genes, such as tumor-suppressor and DNA-repair genes, normally protect against cancer. Mutations in these genes can eliminate that protection.

Oncogenes

Proto-oncogenes produce proteins that regulate cell division and help cells grow. When a proto-oncogene mutates so that it is continually activated (turned on) or is amplified so that there are multiple copies, it becomes an oncogene that overproduces proteins that lead to uncontrolled cell growth and division. Proto-oncogenes are generally converted into oncogenes by one of two mechanisms: a chromosomal rearrangement that moves the gene to a new position where it is constantly “on” or a gene amplification that produces too much of the encoded protein. Point mutations can also activate oncogenes. For example, point mutations in the *Ras* family of oncogenes are present in 15% of all human cancers.

Tumor-suppressor genes

Tumor-suppressor genes produce proteins that suppress or restrain cell growth and division, repair DNA mutations, or initiate apoptosis. When tumor-suppressor genes are mutated, they may fail to make the appropriate proteins. Cells can grow out of control, leading to cancer. While oncogenes are proto-oncogenes that have been activated, tumor-suppressor genes cause cancer when they are inactivated or “turned off.” For example, more than half of all cancers have acquired mutations in the tumor-suppressor gene *TP53* that codes for the tumor-suppressor protein p53.

Cancer genomics

The Human Genome Project, completed in 2003, revealed the entire DNA sequence of human cells and led to advanced sequencing technologies that have enabled researchers to sequence cancer genomes and compare them to the genome sequences of healthy cells. A Cancer Genome Atlas (CGA) was later developed. The landmark program characterized more than 20,000 samples of both cancer genes and normal matches for 33 cancer types. Over 12 years and with more than 11,000 patients contributing information, researchers compiled a huge set of data that is beginning to better show how cancer genetics work. For example, DNA alterations also can occur by fusion, alterations to copy numbers, or complex structural variations. One major finding has been a better understanding of how different tissues share the

KEY TERMS

Allele—Any of the alternative versions of a gene that are present in the population; some alleles increase the risk of specific cancers.

Apoptosis—Programmed self-destruction of a cell.

BRCA1 and BRCA2—Breast cancer susceptibility genes; specific inherited mutations in these genes greatly increase the risk of breast and ovarian cancers.

Cancer Genome Atlas (CGA)—A large multinational initiative for sequencing cancer genomes.

Chronic myelogenous leukemia (CML)—A type of leukemia caused by the *BCR-ABL* oncogene created by a gene fusion resulting from a chromosomal translocation.

Epigenetic—Gene modifications that are independent of the DNA sequence.

Exome—The protein-encoding DNA sequences of the genome.

Gene—A DNA sequence that contains the instructions for producing a specific protein; each gene is normally situated at a precise location on a chromosome.

Gene amplification—The creation of multiple copies of a gene, which can result in the production of excessive amounts of a specific protein.

Gene expression panel—A method for genetically characterizing specific types of cancer.

Genome—The entire DNA sequence of a cell or organism.

HER2—Human epidermal growth factor receptor 2 (EGFR2); also called HER2/neu or erbB-2; a protein overproduced in HER2-positive cancers.

Hereditary nonpolyposis colorectal cancer (HNPCC)—Lynch syndrome; the most common familial cancer syndrome that increases the risk of colorectal cancer; caused by inherited mutations in any of several genes, most of which are involved in DNA repair.

Li-Fraumeni syndrome—A rare familial cancer syndrome characterized by high risk for early-onset breast cancer and soft-tissue sarcomas.

Metastases—Cancers that have spread from the initial (primary) cancer site to other parts of the body.

Mutation—An inherited or spontaneous change in the DNA sequence of a gene.

Nucleotides—The building blocks of DNA and genes.

Oncogene—A proto-oncogene that has developed mutations that can transform a normal cell into a cancer cell; proto-oncogenes promote normal cell growth and division.

Polymerase chain reaction (PCR)—A method for making many copies of DNA or RNA; can be used to detect mutations in genes.

RB1—A cell-cycle control and tumor-suppressor gene; deletion or mutation of RB1 can lead to retinoblastoma.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division, which can create oncogenes, amplify oncogenes, or inactivate a tumor-suppressor gene.

Tumor-suppressor gene—A gene involved in controlling normal cell growth and preventing cancer; mutations in tumor-suppressor genes can promote cancer.

same genetic alterations and resemble one another in tumor biology. On the other hand, some specific cancer types react differently to similar genetic alterations.

Cancer genome sequencing has revealed about 140 genes that when mutated promote or “drive” carcinogenesis. A typical tumor contains 2–8 of these so-called driver gene mutations in oncogenes and tumor-suppressor genes. The driver genes are classified according to which of 12 different cell-signaling pathways they affect or interfere with. These signaling pathways regulate cell fate, cell survival, and genome maintenance. For example, the *APC* gene is most often the first “gatekeeper” or driver mutation in a cell that may eventually

develop into colon cancer. Mutations in the *APC* gene give the cell a growth advantage so that cells with the mutation slowly outgrow neighboring normal colon cells. The occurrence of a second mutation, often in the *KRAS* gene, enables the cell to proliferate much faster. Further mutations in other genes, usually over a period of years, eventually generate a malignant tumor.

Although cancer cells may have hundreds or thousands of point mutations and chromosome translocations, most of these are “passenger” mutations that have little effect on cancer development. Exome sequencing is used to identify mutations only in protein-coding regions of the DNA. Common solid breast, brain, colon, and

pancreatic tumors have an average of 33 to 55 gene mutations that are expected to alter protein products. Most of these are single-base (point) mutations in the DNA sequence. Some cancers, such as melanomas and lung tumors, contain about 200 different mutations, reflecting the effects on DNA of the mutagens ultraviolet light and cigarette smoke, respectively. Tumors with mutations in DNA repair genes can have thousands of mutations, reflecting the inability of the cells to carry out routine DNA repair. In contrast, leukemias and childhood tumors have far fewer mutations—an average of 9.6 per tumor—because the cancers develop over a much shorter period of time.

Tumor cells also have large numbers of epigenetic changes. These are modifications to DNA or histones (the proteins that surround DNA in chromosomes) that change gene expression—the amount of protein that a gene produces. Genome-wide sequencing has revealed previously unidentified driver genes that produce proteins for modifying DNA or histones. These epigenetic effects on gene expression can also promote the growth and proliferation of cancer cells. With advances in cancer genomics, testing can determine how many mutations are present in a tumor (tumor mutational burden) as well as the tumor's stability.

Genetic heterogeneity

In recent years, advanced genome sequencing has revealed that cancerous tumors can have hundreds or thousands of mutations. Furthermore, these mutations can differ significantly among the cells in a single tumor, as well as in tumor metastases—cancers that have spread to other parts of the body from the primary tumor. This means that not only is every cancer genetically unique, but that each cancer itself may contain several genetically distinct populations of cells. In recent years, research teams from around the world have sequenced breast tumor genomes and found that metastases differ genetically from the primary tumor. These metastases apparently evolved from subclones of different cells within the original primary breast tumor. Similar results have been found for pancreatic tumors and their metastases. In a study of large kidney tumors and their metastases, researchers identified 128 different mutations, only about one-third of which were present in all the samples from a single patient, although sometimes there were different mutations within the same cancer genes. Genome sequencing of leukemias has also identified multiple rare genetic subclones of cancer cells from individual patients.

This genetic heterogeneity among tumor cells and metastases has significant implications for diagnosis, treatment, and prognosis. For example, genetic analysis of a single biopsy from a tumor may fail to identify the

QUESTIONS TO ASK YOUR DOCTOR

- Will my cancer be tested for genetic mutations?
- What types of genetic tests will be performed?
- What information will the genetic tests provide?
- Will genetic test results affect my treatment choices?
- Will the genetics of my metastasized cancer be analyzed separately from my primary tumor?

genetic characteristics of all of the tumor cells. Genetic heterogeneity helps explain why cancer treatments are not necessarily effective in all patients with the same type of cancer. Furthermore, it helps explain why newer cancer drugs that target a specific gene mutation almost invariably stop working after a time. The drug may be effective against some, but not all, cancer cells in a tumor. Once the genetically susceptible cells are destroyed, the drug-resistant cells with different mutations can proliferate.

Diagnosis, treatment, and prognosis

Genetic changes in tumor cells can be used to diagnose specific cancers, determine appropriate treatments, and predict whether the cancer is likely to return after treatment. Although most tumors cannot be subjected to whole-genome or exome sequencing, there are various methods for identifying genetic alterations that are common in specific types of cancer. Gene expression panels are used for a number of cancer types, including breast, colon, and prostate cancers. These panels measure the activity (expression) of genes commonly involved in these cancers. The results help in selection of appropriate treatments. For example, the Oncotype Dx breast cancer panel measures the expression of 21 genes, using a method called reverse transcription-polymerase chain reaction (RT-PCR). This method can help predict which patients are most likely to benefit from certain treatments. A 70-gene panel called the MammaPrint is used to analyze breast cancer tumors for their risk of recurrence. Gene amplifications can be detected by cytological staining or by a fluorescent technique called comparative genomic hybridization (CGH).

PCR is used to detect the *BCR-ABL* fusion gene in CML and certain other leukemias. This fusion gene forms when the *ABL* gene from chromosome 9 breaks off and joins the *BCR* gene on chromosome 22 to form the Philadelphia chromosome. PCR is very sensitive—it can

detect the fusion gene, even when there are just a few CML cells among millions of normal cells. PCR is used to confirm diagnoses, monitor disease status, and guide treatment.

Cancer genetic testing is particularly useful for selecting treatments. Targeted therapies for cancer rely on this specific information to better manage the cancer. For example:

- *HER2* is a proto-oncogene that, when amplified to produce multiple copies, becomes an oncogene that causes cells to grow out of control. *HER2*-positive breast cancers do not respond well to some chemotherapy drugs, but specific drugs are available that destroy *HER2*-positive cells. Therefore, breast cancers are routinely tested for *HER2*. *HER2*-positive stomach cancers may also respond to these drugs.
- Specific drugs can target the tyrosine kinase protein produced by the *BCR-ABL* fusion gene in CML.
- Patients with acute myeloid leukemia cells with a mutation in the gene have a poorer prognosis than patients with mutations only in the *NPM1* gene, so a more aggressive treatment, such as a stem cell transplant, may be recommended for cancers with an *FLT3* mutation.
- *KRAS* gene mutations, which occur in 30% to 40% of colorectal tumors, do not respond to some drugs that are used to treat advanced colorectal cancer.
- Lung cancers with *ALK* gene mutations and melanomas and colorectal cancers with specific *BRAF* gene mutations can be targeted with specific drugs.

Hereditary cancer syndromes

Hereditary cancers are caused by genes that are passed down from parents to offspring and that increase the risk of developing specific types of cancer. More than 50 different hereditary cancer syndromes (familial cancers) have been identified. Although rare in the general population, they account for 5% to 10% of all cancers. In general, inheriting a familial cancer gene increases the risk of developing particular cancers, but it does not mean that the individual will necessarily develop cancer. However, familial cancer genes can cause cells to accumulate mutations more quickly and easily, which is why familial cancers tend to occur earlier in life.

Hereditary breast and ovarian cancers were among the first recognized familial cancers and led to the discovery of the *BRCA1* and *BRCA2* tumor-suppressor genes. Certain mutations in these genes confer a very high risk for breast, ovarian, and certain other cancers. However, fewer than 10% of breast and ovarian cancers are caused by these inherited mutations.

Various other familial cancer syndromes are also caused by mutations in tumor-suppressor genes. For example, Li-Fraumeni syndrome is a rare condition associated with many different cancers, most of which develop during childhood or young adulthood. Li-Fraumeni syndrome is most often caused by mutations in the *TP53* gene that encodes the p53 tumor-suppressor protein that normally halts the growth of abnormal cells. *TP53* was the most commonly mutated gene found in cancers as of 2021.

PTEN is a gene that produces a protein that can suppress the growth of cancerous tumors. Mutations in the gene are associated with Cowden syndrome, which is an inherited cancer syndrome associated with increased risk of breast, thyroid, endometrial, and other cancers.

Hereditary nonpolyposis colorectal cancer (HNPCC), or Lynch syndrome, is the most common familial cancer syndrome that increases the risk of colorectal cancer, usually before age 50. It is also associated with various other cancers and can be caused by mutations in various genes, most of which are involved in DNA repair.

Genetic testing

In addition to genetic testing of tumors, genome testing is available for hereditary cancer syndromes such as breast cancer, HNPCC, or mutations in the *RBI* gene that cause retinoblastoma. Individuals who test positive for increased cancer risk may choose to have frequent cancer screenings, make lifestyle changes to decrease their risk, or even undergo prophylactic procedures such as mastectomy (breast removal). Nevertheless, positive genetic tests do not mean that people will necessarily develop a particular cancer. Similarly, negative test results do not mean that they will not develop a particular cancer. Genetic counselors are trained in interpreting test results and in helping people decide whether to undergo genetic testing.

Cardiofaciocutaneous syndrome

Definition

Cardiofaciocutaneous syndrome is an extremely rare genetic condition present at birth characterized by intellectual disability, slow growth, and abnormalities of the heart, face, skin, and hair. There is no cure for cardiofaciocutaneous syndrome. Treatment centers on the

correction of heart abnormalities and strategies to improve the quality of life of the affected individual.

Description

Cardiofaciocutaneous syndrome was first identified and described in 1986 by J. F. Reynolds and colleagues at the Shodair Children's Hospital in Helena, Montana, and at the University of Utah. These physicians identified and described eight children with a characteristic set of mental and physical changes including abnormal skin conditions, an unusual face, sparse and curly hair, heart defects, and intellectual disability. These physicians named the syndrome based on the changes of the heart (cardio), face (facio), and skin (cutaneous). Since that time, physicians have used the descriptions originally put forth by Reynolds to identify other children with cardiofaciocutaneous syndrome.

Scientific research suggests that cardiofaciocutaneous syndrome is associated with a change in the genetic material. However, it is still not known precisely how this change in the genetic material alters growth and development in the womb to cause cardiofaciocutaneous syndrome.

Cardiofaciocutaneous syndrome can sometimes be confused with another genetic syndrome, Noonan syndrome. Children with Noonan syndrome have abnormalities in the same genetic material as those with cardiofaciocutaneous syndrome, and the two syndromes share some similar physical characteristics. Many scientists believe that the two diseases are different entities and should be regarded as separate conditions, while others believe that Noonan syndrome and cardiofaciocutaneous syndrome may be variations of the same disease.

Genetic profile

Recent research has shown that people with cardiofaciocutaneous syndrome have changes in one of four genes: *BRAF*, *MEK1*, *MEK2*, and *KRAS*. Some affected individuals do not have a mutation in one of these genes, suggesting that other genes are also associated with the syndrome.

In almost all cases of cardiofaciocutaneous syndrome, there is no family history of the disease. These cases are thought to represent new genetic changes that occur randomly and with no apparent cause and are termed sporadic. While the cause of the genetic change is still unclear, some studies suggest that the age of the father might be important in the genesis of the disease. In 20 cases for which information was available, scientists noted that fathers of affected children tended to be older (average age of 39 years) when the child was conceived. Therefore, it is believed that a change in the genetic material of the father's sperm may occur as the man ages, and that he

KEY TERMS

Autosomal dominant—A pattern of genetic inheritance where only one abnormal gene is needed to display the trait or disease.

Bitemporal constriction—Abnormal narrowing of both sides of the forehead.

Macrocephaly—A head that is larger than normal.

Noonan syndrome—A genetic syndrome that possesses some characteristics similar to cardiofaciocutaneous syndromes. It is unclear whether the two syndromes are different or two manifestations of the same disorder.

Sporadic—Isolated or appearing occasionally with no apparent pattern.

may, in turn, pass this genetic change to the child, resulting in cardiofaciocutaneous syndrome.

Only one abnormal gene in a gene pair is necessary to display the disease. This is an example of a dominant gene (i.e., the abnormal gene of the gene pair dominates over the normal gene, resulting in the syndrome).

Demographics

Cardiofaciocutaneous syndrome is an extremely rare condition. Because the syndrome is relatively new and only a small number of physicians have actual first-hand experience with the diagnosis of the syndrome, some children with the syndrome may not be diagnosed, particularly if they are living in areas where sophisticated medical care is not available. As a result, it is difficult to know how many children are affected by cardiofaciocutaneous syndrome. However, scientists estimate that at least 800 children worldwide are affected by this condition as of 2021.

Because the syndrome is so rare, it is not known whether the disease is distributed equally among different geographic areas or whether different ethnic groups have higher incidences of the syndrome.

Signs and symptoms

Individuals with cardiofaciocutaneous syndrome have distinct malformations of the head and face. An unusually large head (macrocephaly), a prominent forehead, and abnormal narrowing of both sides of the forehead (bitemporal constriction) are typical. A short, upturned nose with a low nasal bridge and prominent external ears that are abnormally rotated toward the

back of the head are also seen. In most cases, affected individuals have downward slanting eyelid folds, widely spaced eyes, drooping of the upper eyelids, inward deviation of the eyes, and other eye abnormalities. In addition to having unusually dry, brittle, curly scalp hair, affected individuals may lack eyebrows and eyelashes.

Individuals with cardiofaciocutaneous syndrome may also have a range of skin abnormalities, varying from areas of skin inflammation to unusually dry, thickened, scaly skin over the entire body. Most affected individuals also have congenital heart defects, particularly obstruction of the normal flow of blood from the right chamber of the heart to the lungs and/or an abnormal opening in the wall that separates two of the heart chambers.

In addition, most individuals with the disorder experience growth delays, mild to severe intellectual disability, and abnormal delays in the acquisition of skills requiring the coordination of muscular and mental activity. Other abnormalities encountered in children with cardiofaciocutaneous syndrome include seizures, abnormal movements of the eye, poor muscle tone, and poor digestion. In some cases, additional abnormalities may be present.

Diagnosis

The diagnosis of cardiofaciocutaneous syndrome relies on a physical exam by a physician familiar with the condition and radiographic evaluation, such as the use of x-rays or ultrasound to define abnormal or missing structures that are consistent with the criteria for the condition. Although a diagnosis may be made in a newborn, most often the features do not become fully evident until early childhood.

There is no laboratory blood test that can be used to identify people with cardiofaciocutaneous syndrome. However, because the condition is so rare, molecular genetic testing is available for mutations in the four genes known to cause CFC syndrome.

Cardiofaciocutaneous syndrome can be differentiated from Noonan syndrome by the presence of nervous system abnormalities, such as low muscle tone, seizures, and abnormal movements of the eye, as well as by typical changes in the hair and skin.

Treatment and management

There is no cure for cardiofaciocutaneous syndrome. The genetic change responsible for cardiofaciocutaneous syndrome is present in every cell of the body and, as of 2021, there was no means of correcting this genetic abnormality.

Treatment of the syndrome is variable and centers on correcting the different manifestations of the condition. For

QUESTIONS TO ASK YOUR DOCTOR

- What do we know about the genetic basis of cardiofaciocutaneous syndrome?
- How soon after birth can a child with cardiofaciocutaneous syndrome be diagnosed, and on what basis is that diagnosis made?
- What early treatments are available for cardiofaciocutaneous syndrome?
- What is the average lifespan for a child born with cardiofaciocutaneous syndrome, and what factors affect that prognosis?

children with heart defects, surgical repair is often necessary. This may take place shortly after birth if the heart abnormality is life threatening, but often physicians will prefer to attempt a repair once the child has grown older and the heart is more mature. For children who experience seizures, lifelong treatment with antiseizure medications is often necessary. Oral or topical medications may also be used to treat the inflammatory skin conditions and provide some symptomatic and cosmetic relief.

During early development and progressing into young adulthood, children with cardiofaciocutaneous syndrome should be educated and trained in behavioral and mechanical methods to adapt to their disabilities. This program is usually initiated and overseen by a team of healthcare professionals including a pediatrician, physical therapist, and occupational therapist. A counselor specially trained to deal with issues of disabilities in children is often helpful in assessing problem areas and encouraging healthy development of self-esteem. Support groups and community organizations for people with cardiofaciocutaneous syndrome or other disabilities often prove useful to the affected individual and their families. Specially equipped schools or enrichment programs should also be sought.

Children with cardiofaciocutaneous syndrome should be seen regularly by a team of healthcare professionals, including a pediatrician, medical geneticist, pediatric cardiologist, dermatologist, and neurologist. Consultation with a reconstructive surgeon may be of use if some of the physical abnormalities are particularly debilitating.

Prognosis

The prognosis of children with cardiofaciocutaneous syndrome depends on the severity of the symptoms and

the extent to which appropriate treatments are available. In addition to the physical disabilities, the intellectual disability and other nervous system effects can be severe. Since cardiofaciocutaneous syndrome was discovered relatively recently, very little is known regarding the level of functioning and the average lifespan of individuals affected with the condition.

Carnitine palmitoyltransferase deficiency

Definition

Carnitine palmitoyltransferase (CPT) deficiency refers to two separate hereditary diseases of lipid metabolism, CPT-I deficiency and CPT-II deficiency. CPT-I

deficiency affects lipid metabolism in the liver, with serious physical symptoms including coma and seizures. Two types of CPT-II deficiency are similar in age of onset and type of symptoms to CPT-I deficiency. The third most common type of CPT-II deficiency involves intermittent muscle disease in adults, with a potential for myoglobinuria, a serious complication affecting the kidneys. Preventive measures and treatments are available for CPT-I deficiency and the muscle form of CPT-II deficiency.

Description

Carnitine palmitoyltransferase (CPT) is an important enzyme required by the body to use (metabolize) lipids (fats). CPT speeds up the transport of long-chain fatty acids across the inner mitochondria membrane. This transport also depends on carnitine, also called vitamin B₇.

Until the 1990s, discussion centered on whether defects in a single CPT enzyme were responsible for all the conditions resulting from CPT deficiency. Careful chemical and genetic analysis eventually pointed to two different enzymes: CPT-I and CPT-II. Both CPT-I and CPT-II were shown to play an important role in the metabolism of lipids. CPT deficiency of any type affects the muscles, so these disorders are considered to be metabolic myopathies (muscle diseases), or more specifically, mitochondrial myopathies, meaning myopathies that result from abnormal changes occurring in the mitochondria of the cells as a result of excessive lipid buildup.

Understanding the symptoms of CPT requires some familiarity with the basics of lipid metabolism in muscle cells. Fatty acids (FAs) are the major component of lipids. FAs contain a chain of carbon atoms of varying length. Long-chain fatty acids (LCFAs) are the most abundant type, and have at least 12 carbon atoms. Lipids and glucose (sugar) are the primary sources of energy for the body. Both are converted into energy (oxidized) inside mitochondria, structures within each cell where numerous energy-producing chemical reactions take place. Each cell contains many mitochondria.

A single mitochondrion is enclosed by a double-layer membrane. LCFAs are unable to pass through the inner portion of this membrane without first being bound to carnitine, a type of amino acid. CPT-I chemically binds carnitine to LCFAs, allowing transfer through the inner membrane. However, LCFAs cannot be oxidized inside the mitochondrion while still attached to carnitine, so CPT-II reverses the action of CPT-I and removes carnitine. Once accomplished, LCFAs can proceed to be metabolized. Therefore, deficiency of either CPT-I or CPT-II results in improper transfer and utilization of LCFAs in the mitochondria.

CPT-I is involved in lipid metabolism in several tissues, most importantly the liver. There, LCFAs are broken down and ketone bodies are produced. Like lipids and glucose, ketone bodies are used by the body as fuel, especially in the brain and muscles. Deficiency of CPT-I in the liver results in decreased levels of ketone bodies (hypoketosis), as well as low blood sugar levels (hypoglycemia). Hypoketosis combined with hypoglycemia in a child can lead to weakness, seizures, and coma. Symptoms can be reversed by glucose infusions, as well as supplementation with medium-chain fatty acids, which do not require CPT-I to produce energy.

As noted, glucose and fatty acids are important energy sources for the body. During exercise, the muscles initially use glucose as their primary fuel. After some time, however, glucose is depleted and the muscles switch to using fatty acids by a chemical process called oxidation. CPT-II deficiency results in a decrease in LCFAs that can be used by the mitochondria, and the muscles eventually exhaust their energy supply. This explains why prolonged exercise may cause an attack of muscle fatigue, stiffness, and pain in people with CPT-II deficiency. The ability to exercise for short periods is not affected. Infections, stress, muscle trauma, and exposure to cold also put extra demands on the muscles and can trigger an attack. Fasting or a diet high in fats and low in carbohydrates (complex sugars) deplete glucose reserves in the muscles and are risk factors as well.

In some cases, CPT deficiency results in the breakdown of muscle tissue, a process called rhabdomyolysis, and it causes some components of muscle cells to “leak” into the bloodstream. Myoglobin, the muscle-cell equivalent of hemoglobin in the blood, is one of these components. Myoglobin is filtered from the blood by the kidneys and deposited in the urine, causing myoglobinuria. Dark-colored urine is the typical sign of myoglobinuria. Severe and/or repeated episodes of rhabdomyolysis and myoglobinuria can cause serious kidney damage.

Genetic profile

CPT-I deficiency is caused by defects in the *CPT1* gene located on chromosome 11. CPT-II deficiency results from mutations in the *CPT2* gene on chromosome 1.

Both CPT-I and CPT-II deficiency are considered autosomal recessive conditions. This means that both parents of an affected person carry one defective *CPT* gene, but also have a normal gene of that pair. Carriers of a single recessive gene typically do not express the deficiency because the second normal functioning gene is able to compensate. A person with two mutated genes has no normal gene to make up for the deficiency and thus

KEY TERMS

Carnitine—An amino acid necessary for metabolism of the long-chain fatty acid portion of lipids. Also called vitamin B₇.

Fatty acids—The primary component of fats (lipids) in the body. Carnitine palmitoyl transferase (CPT) deficiency involves abnormal metabolism of the long-chain variety of fatty acids.

Hypoglycemia—An abnormally low glucose (blood sugar) concentration in the blood.

Hypoketosis—Decreased levels of ketone bodies.

Ketone bodies—Products of fatty acid metabolism in the liver that can be used by the brain and muscles as an energy source.

Metabolic myopathies—A broad group of muscle diseases whose cause is a metabolic disturbance of some type.

Mitochondria (singular, mitochondrion)—Organelles within the cell responsible for energy production.

Myoglobinuria—The abnormal presence of myoglobin, a product of muscle disintegration, in the urine. Results in dark-colored urine.

Myopathy—Any abnormal condition or disease of the muscle.

Rhabdomyolysis—Breakdown or disintegration of muscle tissue.

expresses the disease. Parents who are both carriers for the same autosomal recessive condition face a 25% chance in each pregnancy that they will both pass on the defective gene and have an affected child.

Several individuals proven to be carriers of CPT-II deficiency have had mild symptoms of the disorder. Measurement of CPT-II enzyme levels (the protein coded for by *CPT2*) in most of the carriers tested show lower levels, as would be expected when one gene is mutated and the other is not. It is not yet clear why some carriers show mild symptoms, but this phenomenon occasionally occurs in other autosomal recessive conditions.

Demographics

CPT-I deficiency is rare, with fewer than 50 cases having been reported. CPT-II deficiency is more common, with more than 300 reported cases, but its true occurrence is unknown. Muscle CPT-II deficiency makes up the majority of cases that have been reported; liver and multiorgan CPT-II deficiency are both quite rare. There

seems to be no geographic area or ethnic group that is at greater risk for either type of CPT deficiency.

Approximately equal numbers of males and females with CPT-I deficiency have been seen, which is typical of autosomal recessive inheritance. However, about 80% of those individuals diagnosed with CPT-II deficiency are male. Males and females do have an equal likelihood of inheriting a defective *CPT2* gene from a parent, but the effects of the gene in each sex can be different. Hormonal differences between males and females may have some effect—a clue being the tendency of an affected woman to have more symptoms while pregnant.

Signs and symptoms

CPT-I deficiency

The CPT-I enzyme has two forms, coded for by different genes. CPT-IA is the form present in liver, skin, kidney, and heart cells, while CPT-IB functions in skeletal muscle, heart, fat, and testis cells. CPT-I deficiency refers to the CPT-IA form since a defective CPT-IB enzyme has not yet been described in humans. CPT-I deficiency has always been diagnosed in infants or children.

The brain and muscles use ketone bodies as a source of energy. The brain especially relies heavily on ketone bodies for energy during times of stress, such as after fasting when low sugar levels (hypoglycemia) occur. In fact, children with CPT-I deficiency are usually first diagnosed after they have fasted due to an illness or diarrhea. Hypoketosis and hypoglycemia in CPT-I deficiency can become severe, and result in lethargy (lack of physical energy), seizures, and coma.

CPT-II deficiency

CPT-II deficiency is divided into three subtypes. Muscle CPT deficiency is the most common form of the condition. Onset of symptoms is usually in adolescence or adulthood, but varies. Hepatic CPT-II deficiency is rare and is diagnosed in childhood. The remaining cases are classified as multiorgan CPT-II deficiency, and have been diagnosed in infants. Differences in the severity of symptoms between the groups, as well as within each group, are due in part to different mutations in the *CPT2* gene. Environmental factors may assist the triggering of attacks and thus may contribute to the variety of observed symptoms.

MUSCLE CPT-II DEFICIENCY. Muscle fatigue, stiffness, and pain are typically caused by prolonged exercise or exertion. Other possible triggers include fasting, infection, muscle injury, exposure to cold, and even emotional stress. Cases of adverse reactions to certain types of general anesthesia have also been reported.

These muscle attacks after a triggering event are the classic physical signs of muscle CPT-II deficiency. When an attack is associated with the breakdown of muscle tissue (rhabdomyolysis), myoglobinuria is the other classic sign. Unlike other metabolic myopathies, there are no obvious signs of an impending attack, and resting will not stop the symptoms once they have begun. Muscle symptoms may begin during or up to several hours after prolonged exercise or other triggering events. A specific muscle group may be affected, or generalized symptoms may occur. Muscle weakness between attacks is not a problem, unlike some other metabolic myopathies. In addition, muscle cells examined under the microscope typically appear normal. Some people with muscle CPT deficiency have only had a few attacks in their lifetime, while others may experience several attacks per week. Renal failure due to repeated episodes of myoglobinuria occurs in about 25% of individuals with muscle CPT deficiency.

HEPATIC CPT-II DEFICIENCY. Symptoms and age of onset in hepatic CPT-II deficiency are similar to CPT-I deficiency, primarily coma and seizures associated with hypoketotic hypoglycemia. However, unlike CPT-I deficiency, most infants with liver CPT-II deficiency have had heart problems and have died.

MULTIORGAN CPT-II DEFICIENCY. This type of CPT-II deficiency has only been reported a few times and involves the liver, skeletal muscles, and heart. Infants with this type have all died.

Diagnosis

The symptoms of CPT-I deficiency can be dramatic, but the rare nature of the disease means that some time may elapse while other more common diseases are ruled out. Definitive diagnosis of CPT-I deficiency is made by measuring the activity of the CPT enzyme in fibroblasts, leukocytes, or muscle tissue. Abnormal results on several blood tests are also typical of CPT-I deficiency, but the most important finding is hypoketotic hypoglycemia. Analysis of the *CPT1* gene on chromosome 11 may be possible, but is not yet considered a diagnostic test.

CPT-II deficiency is somewhat more common than CPT-I deficiency. However, the milder symptoms of muscle CPT deficiency and their similarity to other diseases often leads to a wrong diagnosis (misdiagnosis). For example, the symptoms of CPT-II deficiency are sometimes initially diagnosed as fibromyalgia or chronic fatigue syndrome. Misdiagnosis is a special concern for people with muscle CPT-II deficiency, since the use of available preventive measures and treatment are then delayed.

QUESTIONS TO ASK YOUR DOCTOR

- Can you explain the name of this disorder?
- How do the two types of carnitine palmitoyltransferase deficiency differ from each other?
- What forms of treatment for the disorder are available, and how effective are these treatments?
- What is the prognosis for a child born with each type of carnitine palmitoyltransferase deficiency?

Analysis of the CPT-II enzyme levels can confirm the diagnosis, but must be done carefully if performed on any tissue other than a muscle specimen. Direct testing of the *CPT2* gene is available and is probably the easiest method (simple blood sample) of making the diagnosis. If genetic testing shows two mutated *CPT2* genes, the diagnosis is confirmed. However, not all disease-causing mutations in the gene have been discovered, so demonstration of only one mutated *CPT2* gene, or a completely negative test, does not exclude the diagnosis. In those individuals in whom genetic testing is not definitive, the combination of clinical symptoms and a laboratory finding of low levels of CPT-II enzyme activity should be enough to confirm the diagnosis.

Treatment and management

While CPT-I and CPT-II deficiency differ in their typical age of onset and in the severity of their symptoms, treatment of both conditions is similar. Attacks may be prevented by avoiding those situations that lead to them. Someone undergoing surgery should discuss the possibility of alternative anesthetics with their doctor. Most people with CPT deficiency find it necessary to carry or wear some type of identifying information about their condition such as a Medic-Alert bracelet.

Those who find that they cannot avoid a situation known to be a trigger for them should try to supplement their diet with carbohydrates. Since medium-chain fatty acids do not require carnitine to enter the mitochondrion, use of a dietary supplement containing them results in significant improvement in people with CPT-I deficiency and also helps prevent attacks in most people with CPT-II deficiency. The use of carnitine supplements (vitamin B₇) is also helpful for some individuals diagnosed with the deficiency.

Anyone diagnosed with CPT deficiency, or anyone concerned about a family history of CPT deficiency, should

be offered genetic counseling to discuss the most up-to-date treatment and testing options available to them.

Prognosis

Children with CPT-I deficiency improve significantly with treatment. So far, however, all have had some lasting neurological problems, possibly caused by damage to the brain during their first attack. The outlook at this point for infants and children with liver and multiorgan CPT-II deficiency is still poor.

Once a person with muscle CPT-II deficiency is correctly diagnosed, the prognosis is good. While it is impossible for many patients to completely avoid attacks, most people with the condition eventually find the right mix of preventive measures and treatments. CPT-II deficiency then has much less of a harmful impact on their lives. A number of excellent sources of information are available for families affected by CPT deficiency. Any new treatments in the future would likely attempt to directly address the enzyme deficiency, so that normal metabolism of lipids might occur.

Carpenter syndrome

Definition

Carpenter syndrome is a rare hereditary disorder resulting in the premature closing of the cranial sutures, which are the line joints between the bones of the skull, and in syndactyly, a condition characterized by the webbing of fingers and toes. The syndrome is named after G. Carpenter, who first described this disorder in 1901.

Description

Carpenter syndrome is a subtype of a family of genetic disorders known as acrocephalopolysyndactyly (ACPS) disorders. Carpenter syndrome is also called acrocephalopolysyndactyly type II (ACPS II). There were originally five types of ACPS. This number has decreased in recent years because some of these conditions have been recognized as being similar to each other or to other genetic syndromes. For example, it is now agreed that ACPS I, or Noack syndrome, is the same as Pfeiffer syndrome. Researchers have also concluded that the disorders formerly known as Goodman syndrome (ACPS IV) and Summitt syndrome are variants (slightly different forms) of Carpenter syndrome.

All forms of ACPS are characterized by premature closing of the cranial sutures and malformations of the fingers and toes. Individuals diagnosed with Carpenter syndrome have short and broad heads (brachycephaly), the tops of which appear abnormally cone-shaped (acrocephaly). Webbing or fusion of the fingers or toes (syndactyly) and/or the presence of extra fingers or toes (polydactyly) are also characteristic signs of Carpenter syndrome.

The human skull consists of several bony plates separated by a narrow fibrous joint that contains stem cells. These fibrous joints are called cranial sutures. There are

Graphic of human skull (Gale)

six sutures: the sagittal, which runs from front to back across the top of the head; the two coronal sutures, which run across the skull parallel to and just above the hairline; the metopic, which runs from front to back in front of the sagittal suture; and the two lambdoid sutures, which run from side to side across the back of the head. The premature closing of one or more of these cranial sutures leads to skull deformations, a condition called *craniosynostosis*. There are seven types of *craniosynostosis* depending on which cranial suture or sutures are affected: sagittal, bicoronal (both coronal sutures), unicoronal (one coronal suture), coronal and sagittal, metopic, lambdoid and sagittal, and total, in which all the cranial sutures are affected. Individuals affected with Carpenter syndrome show sagittal and bicoronal types of skull malformations.

Genetic profile

Carpenter syndrome is inherited as a recessive non-sex linked (autosomal) condition. The gene responsible for the syndrome has not yet been identified, but it is currently believed that all ACPS syndromes may be the result of genetic mutations—changes occurring in the genes. Genetic links to other syndromes that also result in *craniosynostosis* have been identified. Sixty-four distinct mutations in seven different genes have been linked to *craniosynostosis*. Three of these genes, one located on the short arm of chromosome 8 (8p11), one on the long arm of chromosome 10 (10q26), and another on the short

arm of chromosome 4 (4p16), are related to fibroblast growth factor receptors (FGFRs), which are molecules that control cell growth. Other implicated genes are the *TWIST* gene located on chromosome 7, the *MSX2* gene on chromosome 5, and the *FBN1* gene on the long arm of chromosome 15.

Demographics

Carpenter syndrome and the other ACPS disorders have an occurrence of approximately one in every one million live births. It is rare because both parents must carry the gene mutation in order for their child to have the disease. Therefore, Carpenter syndrome has been observed in cases where the parents are related by blood, though in most cases parents are not related. Parents with one child affected by Carpenter syndrome have a 25% likelihood that their next child will also be affected with the disorder.

Signs and symptoms

Individuals diagnosed with Carpenter syndrome show various types of malformations and deformities of the skull. The two main examples are sagittal and bicoronal *craniosynostosis*. Sagittal *craniosynostosis* is characterized by a long and narrow skull (*scaphocephaly*). This is measured as an increase in the A-P or anterior-to-posterior diameter, which indicates that

KEY TERMS

Acrocephalopolysyndactyly syndromes—A collection of genetic disorders characterized by a cone-shaped abnormality of the skull and partial fusing of adjacent fingers or toes.

Acrocephaly—An abnormal cone shape of the head.

Autosome—Any chromosome not involved in specifying sex.

Brachycephaly—An abnormal thickening and widening of the skull.

Cranial suture—Any one of the seven fibrous joints between the bones of the skull.

Craniosynostosis—Premature, delayed, or otherwise abnormal closure of the sutures of the skull.

Cutaneous syndactyly—Fusion of the soft tissue between fingers or toes resulting in a webbed appearance.

Gene—A building block of inheritance, which contains the instructions for the production of a particular protein, and is made up of a molecular sequence found on a section of DNA. Each gene is found on a precise location on a chromosome.

Hydrocephalus—The excess accumulation of cerebrospinal fluid around the brain, often causing enlargement of the head.

Polydactyly—The presence of extra fingers or toes.

Scaphocephaly—An abnormally long and narrow skull.

Syndactyly—Webbing or fusion between the fingers or toes.

looking down on the top of the skull, the diameter of the head is greater than normal in the front-to-back orientation. Individuals affected with sagittal craniosynostosis also have narrow but prominent foreheads and a larger than normal back of the head. The so-called soft spot found just beyond the hairline in a normal baby is very small or absent in a baby affected with sagittal craniosynostosis.

The other type of skull malformation observed, bicoronal craniosynostosis, is characterized by a wide and short skull (brachycephaly). This is measured as a decrease in the A-P diameter, which indicates that looking down on the top of the skull, the diameter of the head is less than normal in the front-to-back orientation. Individuals affected with this condition have poorly formed

eye sockets and foreheads. This causes a smaller than normal sized eye socket that can cause eyesight complications. These complications include damage to the optic nerve, which can cause a loss of visual clarity; bulging eyeballs resulting from the shallow orbits (exophthalmos), which usually damage the eye cornea; widely spaced eyes; and a narrowing of the sinuses and tear ducts that can cause inflammation of the mucous membranes that line the exposed portion of the eyeball (conjunctivitis).

A further complication of bicoronal craniosynostosis is water on the brain (hydrocephalus), which increases pressure on the brain. Most individuals affected with this condition also have an abnormally high and arched palate that can cause dental problems and protrusion, the thrusting forward of the lower jaw. Coronal and sagittal craniosynostosis are characterized by a cone-shaped head (acrocephaly). The front soft spot characteristic of an infant's skull is generally much larger than normal and it may never close without surgical intervention. Individuals with these skull abnormalities may also have higher than normal pressure inside the skull.

Individuals with Carpenter syndrome often have webbed fingers or toes (cutaneous syndactyly) or partial fusion of their fingers or toes (syndactyly). These individuals also tend to have unusually short fingers (brachydactyly) and sometimes exhibit extra toes, or more rarely, extra fingers (polydactyly).

Approximately one third of Carpenter syndrome individuals have heart defects at birth. These may include: narrowing of the artery that delivers blood from the heart to the lungs (pulmonary stenosis); blue baby syndrome, due to various defects in the structure of the heart or its major blood vessels; transposition of the major blood vessels, meaning that the aorta and pulmonary artery are inverted; and the presence of an extra-large vein called the superior vena cava, that delivers blood back to the heart from the head, neck, and upper limbs.

In some persons diagnosed with Carpenter syndrome, additional physical problems are present. Individuals are often short or overweight, with males having a disorder in which the testicles fail to descend properly (cryptorchidism). Another problem is caused by parts of the large intestine coming through an abnormal opening near the navel (umbilical hernia). In some cases, mild mental retardation has also been observed.

Diagnosis

The diagnosis of Carpenter syndrome is made based on the presence of the bicoronal and sagittal skull

QUESTIONS TO ASK YOUR DOCTOR

- What are the most important physiological characteristics of Carpenter syndrome?
- How is Carpenter syndrome diagnosed?
- What types of treatments are available for Carpenter syndrome, and at what point in a child's life should they be used?
- What kind of lifestyle adjustments may be necessary for a family with a Carpenter syndrome child?

malformation, which produces a cone-shaped or short and broad skull, accompanied by partially fused or extra fingers or toes (syndactyly or polydactyly). Skull x-rays and/or a CT scan may also be used to diagnose the skull malformations correctly. Other genetic disorders are also characterized by the same types of skull deformities and some genetic tests are available for them. Thus, positive results on these tests can rule out the possibility of Carpenter syndrome.

Before birth, ultrasound imaging, a technique used to produce pictures of the fetus, is generally used to examine the development of the skull in the second and third months of pregnancy, but the images are not always clear enough to properly diagnose the type of skull deformity, if present. New ultrasound techniques are being used in Japan, however, that can detect skull abnormalities in fetuses with much higher image clarity.

Treatment and management

Operations to correct the skull malformations associated with Carpenter syndrome should be performed during the first year of the baby's life. This is because modifying the skull bones is much easier at that age and new bone growth—as well as the required bone reshaping—can occur rapidly. Also, the facial features are still highly undeveloped, so a greatly improved appearance can be achieved. Follow-up support by pediatric, psychological, neurological, surgical, and genetic specialists may be necessary.

Individuals with Carpenter syndrome may have vision problems that require consultation with an ophthalmologist, or doctor specialized in the treatment of such problems. Speech and hearing therapy may also be necessary if the ears and the brain have been affected. If the palate is severely malformed, dental consultation may also be necessary. In the most severe cases of Carpenter

syndrome, it may be necessary to treat feeding and respiratory problems that are associated with the malformed palate and sinuses. Obesity is associated with Carpenter syndrome, and dietary management throughout the patient's lifetime may also be recommended.

Webbed fingers or toes (cutaneous syndactyly) may be easily corrected by surgery. Extra fingers or toes (polydactyly) may often be surgically removed shortly after birth.

Surgical procedures also exist to correct some of the heart defects associated with Carpenter syndrome, as well as the testicular disorder of affected males. The abnormal opening of the large intestine near the navel (umbilical hernia or omphalocele) can also be treated by surgery. Additionally, intervention programs for developmental delays are available for affected patients.

Prognosis

Carpenter syndrome is not usually fatal if immediate treatment for the heart defects and/or skull malformations is available. In all but the most severe and inoperable cases of craniosynostosis, it is possible that the affected individual may attain a greatly improved physical appearance. Depending on damage to the nervous system, the rapidity of treatment, and the potential brain damage from excess pressure on the brain caused by skull malformation, certain affected individuals may display varying degrees of developmental delay. Some individuals will continue to have vision problems throughout life. These problems will vary in severity depending on the initial extent of their individual skull malformations, but most of these problems can now be treated.

Caudal dysplasia

Definition

Caudal dysplasia is a total or partial failure of development of the lower vertebrae, including the sacrum (tailbone), which results in associated abnormalities of the lower extremities (legs), spine, kidneys, and gastrointestinal and genitourinary tracts.

Description

Caudal dysplasia is also known as sacral agenesis, sacral regression, caudal aplasia, caudal regression sequence, and sirenomelia. Caudal dysplasia results from a failure of the caudal, or lower, region of the spinal column to form correctly. This abnormal development of the lower spine causes a wide spectrum of other abnormalities. On the mild end of the spectrum, there may be a partial absence of the tailbone with no associated symptoms (sometimes picked up accidentally on x-ray), but on the severe end of the spectrum, there can be complete absence of the kidneys, openings on the spinal cord, and genitourinary, limb, and bowel abnormalities. Some of these more serious abnormalities can be life-threatening. Most infants with caudal dysplasia fall in between the two ends of the spectrum. They may have kidney malformations, gastrointestinal malformations, spinal cord problems, heart abnormalities, and problems with their lower limbs.

Sirenomelia, sometimes called mermaid syndrome, is a rare condition that was once thought to represent the most severe end of the caudal dysplasia sequence. Infants with sirenomelia may have complete fusion of the lower limbs, complete or partial renal agenesis, and severe bowel problems. There is often oligohydramnios, or a low amount of amniotic fluid, during pregnancy. Because of the severity of the defects in this condition, it is generally lethal. As of 2021, sirenomelia was declared to be a separate syndrome.

Caudal dysplasia is caused by a problem with the formation of certain tissues early in pregnancy. The lower spine is usually completely formed by the seventh week of pregnancy. Caudal dysplasia is a primary defect of

formation of the tissues that will become the sacrum, spinal cord, kidneys, and gastrointestinal system.

Genetic profile

Although the genetics of caudal dysplasia are not well understood, two genes are associated with it: *VANGLI*, which is located on the short arm of chromosome 1 (1p13), and *HLXB9*, which causes a rare form of caudal dysplasia known as Currarino syndrome. Some families have shown autosomal dominant inheritance, but more research will be necessary before the exact pattern of inheritance of this disorder is clear. In most cases, it occurs as an isolated event. In some families, there is evidence of an increased incidence of mild scoliosis and spina bifida occulta (opening on one or more of the vertebra without any physical effect) in the parents of children affected with caudal agenesis.

Demographics

Estimates of the incidence of caudal dysplasia range from approximately 1 to 2.5 per 100,000 newborns. Caudal dysplasia occurs equally in males and females. There is an increased rate of caudal dysplasia among infants of diabetic mothers. As many as 16%–22% of infants with caudal dysplasia are born to diabetic mothers, and the risk for a diabetic woman (with poor glucose control) to have an infant with caudal dysplasia is 200 times higher than the average population risk. Diabetes or impaired glucose metabolism is a common problem in pregnancy, with 3%–10% of all pregnancies affected by abnormal glucose metabolism. The exact mechanism by which diabetes causes caudal dysplasia is not well understood.

Caudal dysplasia is a defect of the mesodermal tissue, which develops early in the first trimester of pregnancy. Poor glucose control during the first trimester can lead to an increased risk for the fetus to develop caudal dysplasia. The interaction between poor glucose control and the defects that lead to problems in the mesodermal tissues is not yet well understood.

Most women with an increased risk to have a child with caudal regression have diabetes (often undiagnosed) prior to pregnancy. Gestational diabetes (or diabetes that develops during pregnancy) is a separate entity and should not be confused with diabetes in the first trimester. Gestational diabetes is not associated with an increased risk for caudal dysplasia.

Signs and symptoms

In order to understand the signs and symptoms of caudal dysplasia, it is important to understand early embryonic development. Very early in pregnancy, the cells that will develop into the embryo are organized as

a small round ball. These cells eventually separate into three distinct layers: the endoderm, the mesoderm, and the ectoderm. The endoderm can be thought of as the inside layer. Cells from the endoderm will eventually form into the lining of the digestive tract and the respiratory tract. The mesoderm can be thought of as the middle layer, and the cells of the mesoderm will eventually become the muscles, bones, kidney, heart, and blood vessels. The ectoderm can be thought of as the outside layer. The cells of the ectoderm will eventually become the skin, hair, nails, brain, and nervous system. Caudal dysplasia is the result of an early insult to the tissues of the mesoderm. Since the mesoderm is the tissue that forms the bones, muscles, kidneys, and other tissues, individuals with caudal dysplasia will have problems with these tissues. Any disruption of the development of the mesoderm will lead to disruption of the organs formed from this layer. Impaired glucose metabolism early in pregnancy can lead to an insult that results in the infant having caudal dysplasia. However, since only 16%–22% of mothers of infants with caudal dysplasia have diabetes, there must be other factors that also cause caudal dysplasia. These other factors were not well understood as of 2021.

Caudal dysplasia is a disorder with a wide spectrum of defects. Some individuals are very mildly affected, and some are much more severely affected. Individuals with caudal dysplasia can have some or all of the signs and symptoms.

Spinal cord abnormalities in infants affected with caudal dysplasia include:

- missing or malformed sacrum
- abnormal vertebrae
- cerebellum agenesis
- hydrocephalus
- spina bifida
- scoliosis

Kidney abnormalities include:

- hydronephrosis
- renal failure
- agenesis of the kidney
- hypoplasia of the kidney

Gastrointestinal abnormalities include:

- imperforate anus
- malformed or rotated gut

Heart abnormalities include:

- atrial septal defect
- coarctation of the aorta
- stenosis of the pulmonary valve

Lower limb abnormalities include:

- clubfeet
- missing reflexes
- paralysis or numbness of the legs

Neurological abnormalities include:

- neurogenic bladder (impaired bladder control)
- neurogenic bowel (impaired bowel control)
- motor and sensory nerve abnormalities

Other abnormalities include:

- cleft lip/palate
- diaphragmatic hernia
- hypoplastic lungs
- low-set ears
- tracheo-esophageal fistula (abnormal connection between the trachea and esophagus)

Diagnosis

The diagnosis of caudal dysplasia can be made during pregnancy, at birth, and during childhood, depending on the severity of the defects present.

Prenatal diagnosis

The diagnosis of caudal dysplasia can be made prenatally (during pregnancy) by prenatal ultrasound (a sonogram). Sonograms use sound waves to provide an image of a fetus. The structural abnormalities of caudal dysplasia, including absence of vertebrae, kidney malformations, other spinal cord malformations, and limb abnormalities, can be seen during the second trimester of pregnancy. Because the bones of the sacrum do not ossify, or harden, until approximately 22 weeks of pregnancy, it may be difficult to diagnose caudal dysplasia before this time.

The diagnosis of caudal dysplasia can also be made by physical examination after birth. Physical signs can include flattening of the buttocks, shortening of the gluteal cleft, scoliosis, spina bifida, and hydrocephalus. X-rays should be taken to look at the formation of the underlying bones and tissues.

Treatment and management

Pregnancy management

When caudal dysplasia is diagnosed by prenatal ultrasound, the mother should be tested for diabetes. Pregnancy termination may be an option. If the pregnancy continues, the parents may wish to consult with specialists to get more specific information about prognosis.

KEY TERMS

Aplasia—Defective development resulting in absence of all or part of an organ or tissue.

Caudal—Pertaining to the tail (bone).

Dysplasia—Abnormal development of tissues, organs, or cells.

Sacrum—Triangular bone at the base of the spinal column.

Delivery management

Because of the abnormalities seen and the possible complications, delivery should be at a tertiary care center or hospital able to provide specialized pediatric care. It is likely that an infant with caudal dysplasia will spend a significant amount of time in the hospital as a newborn. If the tertiary care center is not located near the family, this can increase the burden of care for the family.

There is no cure for caudal dysplasia. Treatment is governed by the abnormalities present. If the abnormalities are severe (life-threatening), corrective surgery is not an option. The main goals of treatments include maintaining and improving kidney, lung, and gastrointestinal function. Orthopedic surgeries are done to correct malformation, and physical therapy is used to avoid secondary complications, such as scoliosis.

Many of the defects of caudal dysplasia can be surgically treated but not cured. For example, an opening on the spine (spina bifida) can be surgically closed, but if the nerves in that opening have been damaged, there is nothing that can be done to reverse this damage. Other surgeries include orthopedic surgeries to correct bone malformations and improve limb function. Surgery can also be done to correct hydrocephalus or imperforate anus.

Other treatments involve orthopedic devices and treatments for neurogenic bladder. Orthopedic devices may be used to help with problems of the hip, back, and legs. Neurogenic bladder is one of the more serious and debilitating problems in caudal dysplasia. Long-term bladder dysfunction can result in kidney damage and failure.

The treatments for caudal dysplasia often require lifelong medical attention. It is important to prepare the family for this and to stress the need for preventive care (that is, prevention of infections) and vigilance in detecting complications.

Prognosis

The prognosis for caudal dysplasia is highly dependent on the severity of the malformation present. Those

with extremely mild abnormalities may have no or few symptoms. Infants with more serious symptoms may require extensive urologic and orthopedic assistance, including multiple surgeries and lifelong therapies. Neurogenic bladder is one of the more serious and debilitating problems in caudal dysplasia. Long-term bladder dysfunction can result in kidney damage and failure, and intensive efforts may be required to avoid this problem. Some infants with caudal dysplasia are born with lethal abnormalities that are incompatible with life. Infants that do survive generally have normal mental function.

CECR1 gene-recurrent fevers and strokes in children

Definition

The *CECR1* gene produces a protein called adenosine deaminase 2 (ADA2). Mutations (changes) in the *CECR1* gene can cause a condition known as deficiency

KEY TERMS

Adenosine deaminase 2 (ADA2)—The enzyme produced by the *CECR1* gene and required for blood-vessel and immune-system development and maintenance; *CECR1* gene mutations that result in little or no ADA2 can cause recurrent fevers and strokes in children and other syndromes in children and adults.

Aneurysm—A blood-filled stretching of a blood vessel, usually an artery, that can lead to stroke.

Autosomal dominant—A pattern of genetic inheritance in which only one abnormal gene is needed to display the trait or disease.

Autosomal recessive—A pattern of genetic inheritance in which two copies of a mutated gene, one from each parent, must be present for the child to develop the trait or disorder.

Deficiency of adenosine deaminase 2 (DADA2)—Syndromes caused by mutations in the *CECR1* gene.

Inflammation—An immune-system response, usually resulting from irritation, infection, or injury and causing redness, swelling, and pain.

Livedo reticularis—Bluish net-like patterns of skin discoloration caused by blood-vessel abnormalities; usually present in children with recurrent fevers and strokes caused by *CECR1* gene mutations.

Macrophages—Immune-system cells derived from monocytes that both promote and inhibit inflammation, among other activities, and whose normal development is affected by *CECR1* gene mutations.

Polyarteritis nodosa (PAN)—An inflammatory disease that affects all layers of blood vessel walls and may be caused by *CECR1* gene mutations.

Sneddon syndrome—Adenosine deaminase 2 deficiency that may be caused by mutations in the *CECR1* gene, with symptoms usually developing later than those of polyarteritis nodosa.

Stroke—An obstruction (ischemic) or rupture (hemorrhagic) of a blood vessel in the brain, causing death of brain tissue and potentially affecting physical and mental functioning.

Vasculitis—Blood vessel inflammation.

of ADA2 (DADA2). DADA2 is characterized by inflammation in various tissues throughout the body, but especially in the blood vessels, resulting in a condition known as vasculitis. DADA2 can be severely disabling or life threatening and has recently been identified as a cause of recurrent fevers and strokes in children.

Description

Adenosine deaminases 1 and 2 are very important enzymes that regulate the levels of the signaling molecule adenosine, which is critical for controlling a variety of cellular functions. ADA1 has long been known to activate immune system cells, but the structure and functions of the very similar ADA2 have only recently begun being elucidated. ADA2, encoded by the *CECR1* gene, is essential for maintaining the integrity of blood vessel walls. ADA2 also functions as a growth factor that is involved in the growth and development of immune system cells, especially the differentiation of monocytes into macrophages and the proliferation of macrophages. Macrophages have critical roles in both promoting and inhibiting inflammation.

Inflammation is the immune system's response to injury and to pathogens such as bacteria. Researchers

have found that ADA2 deficiency (DADA2) causes monocytes/macrophages to attack the body's own blood vessels, leading to uncontrolled inflammation that can damage organs, including the skin, digestive system, kidneys, and nervous system. In particular, blood vessel damage from DADA2 can cause a variety of problems, including stroke, the narrowing or blockage of blood vessels in the brain that can damage and destroy brain tissue by starving it of its blood supply.

With the discovery of mutations in the *CECR1* gene, researchers have realized that DADA2 may be responsible for a variety of previously unexplained syndromes affecting both children and adults. These include recurrent intermittent fevers and recurrent strokes in children that begin in the first years of life. These strokes affect deep-brain structures and may cause permanent brain damage. In children, as in adults, strokes can affect physical, intellectual, and emotional functioning and cause blindness or deafness. The syndrome of recurrent fevers and strokes in children has often been classified as a type of polyarteritis nodosa (PAN). Childhood-onset PAN is a rare autosomal recessive genetic disorder. In addition to recurrent fevers and ischemic stroke in the small blood vessels of the brain, which can cause neurologic dysfunction, PAN is characterized by areas of net-like mottled

skin discoloration called livedo reticularis. PAN and other types of DADA2 can also result in systemic vasculitis-inflamed blood vessels throughout the body, as well as muscle pain, high blood pressure, or aneurysms (dangerous blood-filled pouches in blood vessel walls that can block vessels or burst and hemorrhage). Some patients with PAN or other forms of DADA2 have an enlarged liver and spleen, as well as immune system deficiencies. PAN in children usually begins before the age of ten and varies greatly in its severity. However, PAN in both adults and children probably has other causes in addition to ADA2 deficiency and/or *CECR1* gene mutations. Other forms of DADA2 also vary greatly in symptoms and severity, as well as in the age of onset.

Genetic profile

The *CECR1* gene that produces ADA2 is named for “cat eye syndrome chromosome region, candidate 1” Cat eye syndrome, also called Schmid-Fraccaro syndrome, is a rare abnormality of chromosome 22 that is unrelated to DADA2. *CECR1* is located on the long arm (q) of chromosome 22 at position 11.2 (22q11.2). In 2014, researchers identified mutations in the *CECR1* gene that were responsible for recurrent fevers and strokes beginning in early childhood, as well as *CECR1* mutations that result in blood vessel inflammation. These mutations seriously reduce or eliminate ADA2. In the original study, researchers identified eight different mutations that eliminated the production of ADA2; three of these mutations were present in multiple patients. These early patients had either inherited mutated *CECR1* genes from both parent or had a DNA deletion that knocked out the normal copy of the *CECR1* gene. Subsequently, researchers identified a different *CECR1* mutation that, if present in both copies of the *CECR1* gene (one inherited from each parent), resulted in PAN. As of 2015, at least 15 *CECR1* mutations that result in ADA2 deficiency had been identified.

Conditions associated with *CECR1* mutations are inherited in an autosomal recessive manner, meaning that both copies of the *CECR1* gene (one inherited from each parent) must have mutations in order for DADA2 symptoms to develop. Thus, parents of individuals with DADA2 typically do not have signs or symptoms of ADA2 deficiency. However, there is evidence that adults with a single mutated *CECR1* may have a predisposition to adult-onset stroke.

Furthermore, cases of Sneddon syndrome, a progressive condition characterized by livedo reticularis and neurological abnormalities, have also been found to be caused by *CECR1* gene mutations. Sneddon syndrome may be inherited not only in an autosomal recessive pattern, but also in an autosomal dominant manner that

QUESTIONS TO ASK YOUR DOCTOR

- Could my child’s recurrent fevers and strokes be a result of adenosine deaminase 2 deficiency?
- Should my child have genetic testing for *CECR1* gene mutations?
- Should other family members be tested for *CECR1* mutations?
- What treatments are available for my child?
- What is my child’s prognosis?

requires only one defective copy of the *CECR1* gene to result in signs and symptoms of the disorder.

Demographics

Although only a few dozen cases of DADA2 have appeared in the medical literature, it is suspected that ADA2 deficiency may be much more common than previously recognized. Researchers suspect that *CECR1* mutations may be responsible for more common forms of vasculitis and stroke, as well as PAN and Sneddon syndrome. Furthermore, the *CECR1* mutations that can result in PAN are not uncommon in Middle Eastern and Pakistani populations.

Signs and symptoms

The signs and symptoms of ADA2 deficiency caused by *CECR1* gene mutations vary greatly in severity, even among affected patients from the same family. Early-onset recurrent fevers and strokes usually begin between the ages of five months and four years. However, in some cases symptoms do not develop until adulthood. Some patients have hemorrhagic strokes, in which blood vessels in the brain burst and bleed profusely (hemorrhage), as well as ischemic strokes caused by blockage of small blood vessels deep in the brain or brainstem. The neurologic symptoms of stroke can include paralysis, headache, blindness, and altered mental status. Livedo reticularis or other skin rashes affect most children with *CECR1* gene mutations. Some children have blockages of blood vessels in the fingers and toes, leading to cell death. Other symptoms may include aneurysms, blood vessel problems throughout the body, high blood pressure, other neurologic problems, and abdominal pain. Symptoms depend on the organ damage caused by defective blood vessels. In addition to the heart, skin, and nervous system, joints, muscles, the gastrointestinal tract, and the kidneys may be affected. Because DADA2

affects maturation of the immune system, some patients have poorly regulated or deficient immune systems. DADA2 can also cause anemia (red blood cell deficiency) and other blood disorders. At the mildest end of the DADA2 spectrum, individuals may have no symptoms until the development of leg ulcers after age 59.

Signs and symptoms of Sneddon syndrome are neurological abnormalities including headache and dizziness, high blood pressure, heart disease, and/or stroke. Intellectual impairment, memory loss, and other neurologic symptoms may be caused by reduced blood flow to the brain. Sneddon syndrome generally has a later onset than PAN.

Diagnosis

PAN and other blood vessel disorders may be diagnosed by symptoms including fevers, stroke, and skin rashes, as well as complete blood counts, blood vessel studies called arteriography, and tissue biopsy. Blood tests and skin biopsies may reveal immune system deficiencies and other abnormalities. Other than recurrent fevers and strokes in children, diagnosis of ADA2 deficiency may be difficult because the symptoms are so variable, and ADA2 deficiency now appears to underlie multiple symptoms and syndromes that were not previously recognized as related. Genetic testing is available for known *CECR1* mutations.

Treatment and management

There is no specific treatment for recurrent fevers and strokes caused by *CECR1* gene mutations. Some patients respond better than others to immunosuppressive therapies. However, steroid medications, cyclophosphamide, and immune system inhibitors that can reduce inflammation have proved only partially effective in controlling fever, rash, and other symptoms. ADA2 is produced and functions within the bone marrow, and bone marrow transplantation with blood-cell-producing (hematopoietic) stem cells appears to restore ADA2 levels and resolve symptoms of DADA2 in the few patients who have undergone the procedure.

Prognosis

Prognosis for recurrent fevers and strokes in children caused by *CECR1* gene mutations depends on the severity of symptoms. Strokes and other symptoms of DADA2 can cause permanent disability or death, although some abilities lost to stroke—such as walking—can be relearned. Steroids and other immunosuppressive drugs can improve symptoms and increase long-term survival of patients with PAN. However, with so few cases yet identified as *CECR1*-associated, the likeliest prognosis is unknown.

Margaret Alic, PhD

Celiac disease

Definition

Celiac disease is a disease of the digestive system that damages the small intestine and interferes with the absorption of nutrients from food.

Description

Celiac disease occurs when the body reacts abnormally to gluten, a protein found in wheat, rye, barley, and possibly oats. When someone with celiac disease eats foods containing gluten, that person's immune system causes an inflammatory response in the small intestine, which damages the tissues and results in an impaired ability to absorb nutrients from foods. The inflammation and malabsorption create wide-ranging problems in many systems of the body. Since the body's own immune system causes the damage, celiac disease is classified as an autoimmune disorder. Celiac disease may also be called sprue, nontropical sprue, gluten sensitive enteropathy, celiac sprue, and adult celiac disease.

Each person with celiac disease is affected differently. When food containing gluten reaches the small intestine, the immune system begins to attack a substance called gliadin, which is found in the gluten. The resulting inflammation causes damage to the delicate finger-like structures in the intestine called villi, where food absorption actually takes place. This damage is referred to as villus atrophy. The patient may experience a number of symptoms related to the inflammation and the chemicals it releases, and/or the lack of ability to absorb nutrients from food, which can cause malnutrition.

Risk factors

People with autoimmune disorders are more at risk for celiac disease. Since it can run in families, risk is also increased if there is a family history of the condition.

Many disorders are associated with celiac disease, though the nature of the connection is unclear. One type of epilepsy is linked to celiac disease. Once their celiac disease is successfully treated, a significant number of these patients have fewer or no seizures. Patients with alopecia areata, a condition in which hair loss occurs in sharply defined areas, have been shown to have a higher risk of celiac disease than the general population. There appears to be a higher percentage of celiac disease among people with Down syndrome, but the link between the conditions is unknown.

Several conditions attributed to a disorder of the immune system have been associated with celiac disease. People with insulin dependent diabetes (type 1) have a much higher incidence of celiac disease. One source estimates that as many as 1 in 10 insulin-dependent diabetics may have celiac disease. Patients with juvenile chronic arthritis, some thyroid diseases, and IgA deficiency are also more likely to develop celiac disease.

There is an increased risk of intestinal lymphoma, a type of cancer, in individuals with celiac disease.

Illustration of healthy villi (left) and inflamed villi affected by celiac disease (right). When people with celiac disease eat foods or use products containing gluten, their immune system responds by damaging the villi. (joshya/Shutterstock)

Successful treatment of celiac disease seems to decrease the chance of developing lymphoma.

Genetic profile

The exact cause of celiac disease is unknown. It can run in families and has a genetic basis, but the pattern of inheritance is complicated. The type of inheritance pattern that celiac disease follows is called multifactorial (caused by many factors, both genetic and environmental). Researchers think that several factors must exist in order for the disease to occur. First, the patient must have a genetic predisposition to develop the disorder. Then, something in their environment acts as a stimulus to trigger their immune system, causing the disease to become active for the first time. For conditions with multifactorial inheritance, people without the genetic predisposition are less likely to develop the condition with exposure to the same triggers. Or, they may require more exposure to the stimulus before developing the disease than someone with a genetic predisposition. Several factors may provoke a reaction; these include surgery, especially gastrointestinal surgery; a change to a low-fat diet, which has an increased number of wheat-based foods; pregnancy; childbirth; severe emotional stress; or a viral infection. This combination of genetic susceptibility and an outside agent leads to celiac disease.

Demographics

Celiac disease may be discovered at any age, from infancy through adulthood. The disorder is more commonly found among white Europeans or in people of European descent. It is very unusual to find celiac disease in African or Asian people. The exact incidence of the disease is uncertain. Estimates vary from 1 in 5,000, to as many as 1 in every 300 individuals with this background. The prevalence of celiac disease seems to be different from one European country to another and between Europe and the United States. This may be due to differences in diet and/or unrecognized disease. A recent study of random blood samples tested for celiac disease in the United States showed 1 in 250 testing positive. It is clearly underdiagnosed, probably because of the symptoms being attributed to another problem or lack of knowledge about celiac disease by physicians and laboratories.

Because celiac disease has a hereditary influence, close relatives (especially first-degree relatives, such as children, siblings, and parents) have a higher risk of being affected with the condition. The chance that a first-degree relative of someone with celiac disease will have the disease is about 10%.

As more is learned about celiac disease, it becomes evident that there are many variations that may not produce typical symptoms. It may even be clinically “silent,” where no obvious problems related to the disease are apparent.

Signs and symptoms

The most commonly recognized symptoms of celiac disease relate to the improper absorption of food in the gastrointestinal system. Many patients with gastrointestinal symptoms will have diarrhea and fatty, greasy, unusually foul-smelling stools. The patient may complain of excessive gas (flatulence), distended abdomen, weight loss, and generalized weakness. Not all people have digestive system complications; some people only have irritability or depression. Irritability is one of the most common symptoms in children with celiac disease.

Not all patients have these problems. Unrecognized and untreated celiac disease may cause or contribute to a variety of other conditions. The decreased ability to digest, absorb, and utilize food properly (malabsorption) may cause anemia (low red blood count) from iron deficiency or easy bruising from a lack of vitamin K. Poor mineral absorption may result in osteoporosis, or “brittle bones,” which may lead to bone fractures. Vitamin D levels may be insufficient and bring about a softening of bones (osteomalacia), which produces pain and bony deformities, such as flattening or bending. Defects in the tooth enamel characteristic of celiac disease may be recognized by dentists. Celiac disease may be discovered during medical tests performed to investigate failure to thrive in infants, or lack of proper growth in children and adolescents. People with celiac disease may also experience lactose intolerance because they do not produce enough of the enzyme lactase, which breaks down the sugar in milk into a form the body can absorb. Other symptoms can include muscle cramps, fatigue, delayed growth, tingling or numbness in the legs (from nerve damage), pale sores in the mouth (called aphthous ulcers), tooth discoloration, or missed menstrual periods (due to severe weight loss).

A distinctive, painful skin rash called dermatitis herpetiformis may be the first sign of celiac disease. Approximately 10% of patients with celiac disease have this rash, but it is estimated that 85% or more of patients with the rash have the disease.

Diagnosis

Examination

Because of the variety of ways celiac disease can manifest itself, it is often not diagnosed promptly. Its symptoms are similar to many other conditions, including

irritable bowel syndrome, Crohn's disease, ulcerative colitis, diverticulosis, intestinal infections, chronic fatigue syndrome, and depression. The condition may persist without diagnosis for so long that the patient accepts a general feeling of illness as normal. This leads to further delay in identifying and treating the disorder. It is not unusual for the disease to be identified in the course of medical examinations for seemingly unrelated problems.

Tests

If celiac disease is suspected, a blood test can be ordered. This test looks for the antibodies to gluten (called antigliadin, anti-endomysium, and antireticulin) that the immune system produces in celiac disease. Antibodies are chemicals produced by the immune system in response to substances that the body perceives to be threatening. Some experts advocate not just evaluating patients with symptoms, but using these blood studies as a screening test for high-risk individuals, such as those with relatives (especially first-degree relatives) known to have the disorder. An abnormal result points toward celiac disease, but further tests are needed to confirm the diagnosis. Because celiac disease affects the ability of the body to absorb nutrients from food, several tests may be ordered to look for nutritional deficiencies. For example, doctors may order a test of iron levels in the blood because low levels of iron (anemia) may accompany celiac disease. Doctors may also order a test for fat in the stool, since celiac disease prevents the body from absorbing fat from food.

Procedures

If celiac disease is suspected, a biopsy (removal of a tiny piece of tissue surgically) of the small intestine can be performed. This is usually done by a gastroenterologist, a physician who specializes in diagnosing and treating bowel disorders. It is generally performed in the office, or in a hospital's outpatient department. The patient remains awake but is sedated. A narrow tube called an endoscope is passed through the mouth, down through the stomach, and into the small intestine. A small sample of tissue is taken and sent to the laboratory for analysis. If it shows a pattern of tissue damage characteristic of celiac disease, the diagnosis is established.

The patient is then placed on a gluten-free diet (GFD). The physician will periodically recheck the level of antibodies in the patient's blood. After several months, the small intestine is biopsied again. If the diagnosis of celiac disease was correct (and the patient followed the rigorous diet), healing of the intestine will be apparent. Most experts agree that it is necessary to follow these steps in order to be sure of an accurate diagnosis.

QUESTIONS TO ASK YOUR DOCTOR

- What does gluten do to people with celiac disease?
- What caused my celiac disease?
- How can I manage my celiac disease?
- What are the treatment options?
- What kinds of tests will I need to confirm that I have celiac disease?
- Where can I get information about maintaining a gluten-free diet?
- Is my condition likely to improve over time, stay the same, or get worse?
- What is the likelihood that my disorder will be transmitted to any children I may have in the future?

Treatment and management

Traditional

The only treatment for celiac disease is a gluten-free diet. This may be easy for the doctor to prescribe but difficult for the patient to follow. For most people, adhering to this diet will stop symptoms and prevent damage to the intestines. Damaged villi can be functional again in three to six months. This diet must be followed for life. For people whose symptoms are cured by the gluten-free diet, this is further evidence that their diagnosis is correct.

Gluten is present in any product that contains wheat, rye, barley, or oats. It helps make bread rise and gives many foods a smooth, pleasing texture. In addition to the many obvious places gluten can be found in a normal diet, such as breads, cereals, and pasta, there are many hidden sources of gluten. These include ingredients added to foods to improve texture or enhance flavor and products used in food packaging. Gluten may even be present on surfaces used for food preparation or cooking.

Fresh foods that have not been artificially processed, such as fruits, vegetables, and meats, are permitted as part of a GFD. Gluten-free foods can be found in health food stores and in some supermarkets. Mail-order food companies often have a selection of gluten-free products. Help in dietary planning is available from dietitians (health-care professionals specializing in food and nutrition) or from support groups for individuals with celiac disease. There are many cookbooks on the market specifically for those on a GFD.

Treating celiac disease with a GFD is almost always completely effective. Gastrointestinal complaints and other symptoms are alleviated. Secondary complications, such as anemia and osteoporosis, resolve in almost all patients. People who have experienced lactose intolerance related to their celiac disease usually see those symptoms subside as well. Although there is no risk and much potential benefit to this treatment, it is clear that avoiding all foods containing gluten can be difficult.

Experts emphasize the need for lifelong adherence to the GFD to avoid the long-term complications of this disorder. They point out that although the disease may have symptom-free periods if the diet is not followed, silent damage continues to occur. Celiac disease cannot be “outgrown” or cured, according to medical authorities.

Prevention

There is no way to prevent celiac disease. However, the key to decreasing its impact on overall health is early diagnosis and strict adherence to the prescribed gluten-free diet.

Prognosis

Treating celiac disease with a strict GFD is almost always completely effective. Gastrointestinal complaints and other symptoms are alleviated. Secondary complications, such as anemia and osteoporosis, resolve in almost all patients. People who have experienced lactose intolerance related to their celiac disease usually see those symptoms subside as well.

Patients with celiac disease must adhere to a strict GFD throughout their lifetime. Once the diet has been followed for several years, individuals with celiac disease have mortality rates similar to those of the general population. However, about 10% of people with celiac disease develop a cancer involving the gastrointestinal tract (both carcinoma and lymphoma).

There are a small number of patients who develop a refractory type of celiac disease, where the GFD no longer seems effective. Once the diet has been thoroughly assessed to ensure no hidden sources of gluten are causing the problem, medications may be prescribed. Steroids or immunosuppressant drugs are often used to try to control the disease. It is unclear whether these efforts meet with much success.

Cell-free DNA test

Definition

Cell-free DNA testing is a procedure for identifying fragments of disintegrated DNA in blood serum that have been released from dying cells or tumor cells, amplifying

the fragments by polymerase chain reaction (PCR), and using next-generation sequencing methods to identify genetic mutations in the targeted DNA.

Cell-free DNA is also referred to as cfDNA or circulating DNA. Such specific subtypes of cfDNA as cell-free fetal DNA, cell-free tumor DNA, and donor-derived cell-free DNA are abbreviated as cffDNA, ctDNA, and ddcfDNA, respectively.

Description

All living cells in humans actively release fragments of DNA and other nucleic acids into the blood. This release has been variously attributed to apoptosis, or programmed cell death; cell lysis; or spontaneous mechanisms of DNA release that are not yet fully understood. Apoptosis is characterized by the activation of certain enzymes that cut or cleave the DNA in the dying cell into smaller units about 180 base pairs (bp) in length. This process, known as DNA fragmentation, is a consequence rather than a cause of apoptosis. Cell lysis occurs when the membrane of a cell breaks down as the result of osmotic pressure or the activity of a virus or an enzyme. The average level of cfDNA in a healthy adult human varies between 10 and 30 nanograms per milliliter (ng/mL), which is a low concentration that presents an ongoing challenge to current recovery methods.

Cell-free fetal DNA is produced by cells in the trophoblast, the collection of cells that surrounds the embryo from the time it implants in the wall of the mother's uterus. The trophoblast cells eventually form the placenta, the organ that allows for exchange of nutrients and waste products between the fetus's blood circulation and the mother's. As early as seven weeks of gestation, microparticles from the trophoblast cells containing fragmented DNA from the fetus are shed into the mother's bloodstream. The fragments of cell-free fetal DNA are significantly smaller (about 200 bp) than the DNA fragments in the mother's blood, so they can be separated from the mother's cell-free DNA on the basis of size. The proportion of cffDNA in the mother's blood increases over the course of the pregnancy up until childbirth.

Whether from DNA fragmentation following apoptosis, cell lysis, or spontaneous release from living cells, cell-free DNA has only a brief half-life in blood plasma. It is estimated that the half-life of cell-free DNA ranges from 15 minutes to several hours. It is cleared from the blood by the liver and kidneys. In the case of cell-free fetal DNA, cffDNA is cleared from the mother's blood within 2 hours of delivery.

Cell-free nucleic acids (cfNAs) were first identified in human blood plasma in 1948 by two French scientists, but it was not until the late 1970s that cancer patients

were found to have higher levels of circulating DNA than healthy persons, and not until the 1990s that genetic mutations in the cell-free DNA of cancer patients were identified. In 1997, cell-free fetal DNA was first detected in maternal blood, but the trophoblast was not identified as the source of the cffDNA until 2007. The introduction of so-called high-throughput or next-generation sequencing methods in 2005 has allowed for the detection of mutations in cell-free DNA with a very high degree of specificity and accuracy and for the introduction of the first noninvasive screening test for fetal chromosomal abnormalities in 2011.

Purpose

Cell-free DNA testing had only one clinical application as of 2015, which was as a noninvasive screening test using cell-free fetal DNA to look for genetic abnormalities in high-risk pregnancies without the risk of causing loss of the pregnancy. Cell-free fetal DNA testing can also be used for paternity testing and early identification of fetal sex, but it is not presently used as a diagnostic test. If the cffDNA screening test indicates the possibility of a chromosomal abnormality in the fetus, the mother is asked to return for additional tests that are considered definitively diagnostic.

Cell-free DNA testing is presently being used in research in other areas of medicine, particularly cancer therapy, organ transplantation, and inflammatory conditions and disorders. Cell-free DNA testing is presently used in cancer diagnostics to provide genetic profiles of cancers and monitor the results of treatment.

Method

Cell-free DNA is obtained from samples of the patient's blood. It is considered a noninvasive test because it does not require surgical removal of tissue, as in a biopsy, or the insertion of endoscopes or similar instruments into the patient's body cavities. No special preparation on the patient's part is required for the blood test.

After the blood is withdrawn by venipuncture into a test tube containing an anticoagulant, the tube is sent to the laboratory, where it is first centrifuged to separate the blood cells from the plasma (the liquid portion of blood). The cell-free DNA is in the plasma and must be isolated and purified; this process is usually done with commercially available kits. The separation of the plasma from the cells in the blood sample must be done quickly before the white cells in the blood disintegrate and release genomic DNA into the sample.

In the case of cell-free fetal DNA testing, the fetal DNA must be separated from the mother's DNA. To

prevent the further release of maternal DNA from any blood cells in the sample, formaldehyde is added to the plasma. The DNA fragments are then separated by size to increase the proportion of fetal DNA in the final sample. Most laboratories consider a fetal cell-free DNA content of 4% or higher within the cell-free maternal DNA to be necessary to obtain an accurate result; between 2% and 6% of cell-free fetal DNA tests are unsuccessful because the fetal fraction is too low. The results of the test are usually available within 7–10 days after the blood is drawn.

Uses

Cell-free DNA testing has a growing number of uses.

Noninvasive prenatal testing (NIPT)

Cell-free fetal DNA testing has been used since 2011 as a noninvasive prenatal test, or NIPT. Ultrasound is the other form of NIPT. The cffDNA test is performed during or after the tenth week of pregnancy, when measurable amounts of cell-free fetal DNA can be detected in the mother's blood. Between 3% and 13% of cell-free DNA in the mother's blood at ten weeks gestation is of fetal origin. As of 2021, the American College of Obstetricians and Gynecologists (ACOG) recommended the test only as a screener for women at high risk of a chromosomal disorder in their pregnancy. Women are considered to be at high risk if they meet any of the following criteria:

- are age 35 or older
- have had a positive result on a first- or second-trimester maternal serum screening test
- have had an ultrasound that indicates the possibility of a chromosomal abnormality in the fetus
- have had a previous pregnancy with a trisomy
- have a known balanced chromosome translocation in either father or mother linked to trisomies 13, 18, or 21

The patient should receive genetic counseling prior to the test.

As of mid-2021, ACOG did not recommend cell-free fetal DNA testing as routine screening for women with low-risk pregnancies because the accuracy of the results has not yet been adequately tested. In addition, cffDNA testing is not recommended for women carrying twins, triplets, or other multiple pregnancies. The organization also notes the limitations of cffDNA testing: While it is effective in screening for the most common trisomies—trisomy 13 (Patau syndrome), trisomy 18 (Edwards syndrome), and trisomy 21 (Down syndrome)—it will not detect such abnormalities as neural tube defects or defects of the ventral abdominal wall.

Because the cffDNA test is considered a screener and not a diagnostic test, women who receive abnormal findings should undergo an invasive diagnostic test (usually chorionic villus sampling or amniocentesis) to confirm the diagnosis of a chromosomal abnormality. An important reason for this precaution is that the screening test in its present form yields some false-positive results, and many women do not wait for confirmation but terminate their pregnancies immediately. An article published in the *Boston Globe* in December 2014 described the limitations of present cffDNA screening tests and the importance of closer Food and Drug Administration (FDA) regulation of the companies offering these tests. The ACOG states that any decisions about further management of a pregnancy should never be based on the results of the screening test alone.

Cancer detection and monitoring

Another major area of investigation using cell-free DNA is in cancer diagnosis and therapy. It has been known since the late 1970s that cell-free DNA levels are significantly higher in patients with cancer than in healthy persons and that these increased levels include the patient's normal cell-free DNA as well as cell-free tumor DNA. The level of cell-free tumor DNA (ctDNA) in the patient's blood is broadly proportional to the extent of the disease and increases still further when the cancer metastasizes. The size of ctDNA fragments varies somewhat, but most are between 70 and 200 bp in length.

The amount of ctDNA detected in cancer patients varies somewhat depending on the type of tumor. Cancers of the ovaries and liver, as well as metastatic cancers of the pancreas, urinary bladder, colon, stomach, breast, esophagus, or throat produce measurable amounts of ctDNA, whereas cancers of the central nervous system are less likely to produce detectable amounts; it is thought that the existence of the blood/brain barrier explains this difference.

Cell-free tumor DNA, sometimes referred to as liquid biopsy, is presently used in cancer research for several purposes:

- Diagnosing the genotype of the tumor. Liquid biopsy has an advantage over tissue biopsy not only because it is less invasive but also because it is more accurate. Many solid tumors are genetically heterogeneous, which means that different portions of the tumor have different genetic profiles, and a tissue biopsy may fail to sample some of the evolving mutations within the cancer. A liquid biopsy, on the other hand, would collect cell-free tumor DNA from all parts of the tumor.
- Monitoring the presence of residual disease in patients who have undergone surgery; ctDNA testing could spare

KEY TERMS

Aneuploidy—A condition in which an abnormal number of chromosomes exists in the nucleus of a cell. Trisomy 18 and trisomy 13 are examples of aneuploid conditions.

Apoptosis—The normally programmed cell death process in which cells die in order to be replaced with new cells.

Base pair (bp)—Any of the complementary nucleotide bases (adenine-thymine and cytosine-guanine in DNA; adenine-uracil and cytosine-guanine in RNA) held together by weak hydrogen bonds. Base pairs form links between the two strands of DNA.

Biomarker—In medicine, any substance or other indicator that can be measured to identify the presence or severity of a disease.

Half-life—The amount of time that it takes for a drug, cell, or other component of blood to drop to half of its initial value.

Histocompatibility—The degree to which two people's genetically determined human leucocyte antigen (HLA) alleles (tissue types) match. The higher the level of histocompatibility, the greater the likelihood of successful organ transplantation.

Liquid biopsy—An informal term used to describe the use of cell-free tumor DNA in identifying the presence of cancer, staging it, evaluating its risk of metastasis, and monitoring the effects of treatment on the cancer's progression.

Next-generation sequencing—A general term for massively parallel sequencing of large portions of DNA base pairs, performed by first fragmenting the DNA, reading the individual fragments in parallel, and then reassembling the reads to obtain the sequence of the entire genome.

Noninvasive prenatal testing (NIPT)—Prenatal testing that does not involve methods or techniques that increase the mother's risk of miscarriage. Present forms of NIPT include ultrasound imaging and cell-free fetal DNA testing.

Plasma—The liquid portion of blood and lymphatic fluid that contains antibodies and other proteins.

Polymerase chain reaction (PCR)—A laboratory process used to make a large number of copies of specific genetic information from small amounts of DNA.

Translocation—The transfer of one part of a chromosome to another chromosome during cell division. A balanced translocation occurs when pieces from two different chromosomes exchange places without loss or gain of any chromosomal material. An unbalanced translocation involves the unequal loss or gain of genetic information between two chromosomes.

Trisomy—The condition of having three identical chromosomes, instead of the normal two, in a cell.

some patients unnecessary chemotherapy or radiotherapy by indicating that the surgery was successful in curing the patient.

- Measuring the effectiveness of chemotherapy and radiotherapy in treating the cancer; this measurement is possible because the levels of ctDNA will drop if the patient is responding to these therapies.
- Identifying new mutations in the tumor and the development of genetic resistance to anticancer drugs. This application of cell-free tumor DNA promises to advance the development of personalized medicine (the use of a patient's genetic information to devise highly individualized therapy for his or her cancer).

Transplantation medicine

Researchers have discovered that cell-free DNA produced by a donated organ—called donor-derived cell-free DNA, or ddcfDNA—can be identified in the transplant

recipient's blood and urine during acute rejection of the donated organ. It is thought that improving the ability to measure ddcfDNA in transplant recipients might allow its use as an early noninvasive biomarker of organ rejection.

As with other applications of cell-free DNA measurement, the use of next-generation sequencing techniques makes ddcfDNA a simpler and more accurate way to assess the degree of histocompatibility between organ donor and recipient before transplantation as well as an effective technique for monitoring the success of the transplant. Of the 419 clinical research studies of cell-free DNA registered with the National Institutes of Health as of late summer 2021, two were studies of the use of ddcfDNA as a biomarker in heart and kidney transplantation.

Other biomarker research

Measurement of cell-free DNA is presently used in sports medicine research to evaluate the effects of

QUESTIONS TO ASK YOUR DOCTOR

- What do you think the future holds for cell-free DNA testing?
- What is your opinion of extending the use of cell-free fetal DNA testing to routine pregnancies as well as high-risk ones?
- Do you think personalized medicine for cancer patients will become a reality in the near future?
- What do you see as the possible drawbacks of widespread cell-free DNA testing (issues of confidentiality, potential loss of health insurance, etc.)?

overtraining on skeletal muscle as well as the changes in a subject's immune response following exercise. It is known that intense exercise temporarily raises a person's levels of cfDNA, although the mechanism behind the active cellular release of cfDNA during exercise is still not fully understood.

Inflammation is another biological process that is known to raise the levels of cfDNA in humans. Researchers are presently measuring cell-free DNA levels in burn patients as a marker of the extent and severity of tissue injury and in patients with autoimmune diseases such as systemic lupus erythematosus (SLE) to evaluate response to therapy.

Cenani-Lenz syndrome

Definition

Cenani-Lenz syndrome is a rare genetic disorder characterized by syndactyly, a condition in which two or more digits (fingers or toes) are joined together either by webs of skin or by fusion of the bones of adjoining digits. The word "syndactyly" comes from two Greek words that mean "together" and "finger." The syndrome is also known as Cenani-Lenz syndactyly syndrome (CLSS), Cenani syndactylism, syndactylism type VII, and syndactyly type 7.

The syndrome is named for the two geneticists who first identified it in 1967, Asim Cenani and Widukind Lenz. The two researchers were able to determine that their first patients had a previously unknown disorder rather than a form of Apert syndrome, a type of syndactyly recognized since 1906.

Description

Children with CLSS are born with complex syndactyly of the hands, as well as other skeletal malformations. "Complex syndactyly" refers to fusion of the bones in the fingers (synostosis), as distinct from simple syndactyly, in which the fingers are connected by soft tissue only. In children with CLSS, the syndactyly includes attachment of the thumb to the four fingers, giving the child's hand a

KEY TERMS

Anonychia—The absence or abnormal development of the fingernails and toenails.

Apert syndrome—A genetic syndrome characterized by syndactyly as well as malformations of the skull and face. It is named for Eugène Apert, the French physician who first described it in 1906.

Autosomal recessive—A pattern of inheritance in which two copies of a defective gene on a nonsex chromosome must be present for a disease or inherited trait to develop in an individual.

Autosome—Any human chromosome other than a sex chromosome.

Congenital—Present at birth.

Consanguinity—The property of belonging to the same blood kinship as another person. In genetics, marriages between two people who are second cousins or closer are regarded as consanguineous unions.

Frontal bossing—The medical term for an unusually prominent forehead, often associated with an abnormally heavy brow ridge.

Hypertelorism—A birth defect in which the child's eyes are spaced abnormally far apart.

Hypothyroidism—A condition in which the patient's thyroid gland does not produce enough thyroid hormone.

Oligodactyly—The absence of one or more fingers on a hand or toes on a foot.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than 10 degrees to the right or left as the doctor faces the patient.

Spoon hand—A type of syndactyly in which the thumb is joined to the four fingers as well as the fingers being fused together. It is also known as "mitten hand."

Syndactyly—A birth defect in which the fingers or toes are joined either by webs of soft tissue (simple syndactyly) or by fusion of the bones (complex syndactyly). Syndactyly may occur either as an isolated birth defect or as part of a genetic syndrome like CLSS.

Synostosis (plural, synostoses)—The medical term for the fusion of two bones.

mitten- or spoon-shaped appearance. This malformation is sometimes referred to as "mitten hand" or "spoon hand."

In addition to complex syndactyly, children with CLSS typically have abnormally short forearm bones; these bones may also be fused together. Malformations of the feet and toes are also common, as are scoliosis and other deformities of the spinal column. In some cases, some of the child's fingers or toes are completely missing (oligodactyly) and facial features are deformed.

Genetic profile

Most known cases of Cenani-Lenz syndrome have been traced to mutations in the *LRP4* gene on chromosome 11 at 11p12–p11.2. At least two families with histories of CLSS, however, were found to not have *LRP4* mutations, suggesting that mutations in at least one other gene might also produce the syndrome. In May 2015, a team of geneticists based in Saudi Arabia reported tracing a new group of CLSS cases to mutations in the *APC* gene located on chromosome 5 at 5q22. This finding is the first time that mutations of this gene have been linked to a syndrome unrelated to cancer. Defects in the *APC* gene have long been associated with colorectal cancer, as the

gene normally codes for a protein that acts as a tumor suppressor.

CLSS is inherited in an autosomal recessive pattern, meaning that two copies of a defective gene, one from each parent, are required in order to produce the syndrome. Parents of one child with CLSS have a 25% chance of having another child with the syndrome in each successive pregnancy.

Consanguinity, or intermarriage among blood relatives, increases the risk of inheriting an autosomal recessive mutation. Most geneticists regard marriages contracted between two persons who are second cousins or closer as consanguineous unions. Worldwide, the most common form of consanguineous marriage is between first cousins, in which husband and wife share one-eighth of their genetic material derived from one common ancestor. It is noteworthy that most of the known cases of Cenani-Lenz syndrome were identified in consanguineous families from Turkey, eastern Asia, Pakistan, and Saudi Arabia.

Demographics

Syndactyly, by itself, is a relatively common birth defect, occurring in 1 of every 2,000–3,000 live births,

and it is associated with nearly 30 different genetic disorders. Cenani-Lenz syndrome, however, is very rare, with only about 30 cases reported worldwide as of 2021. It is estimated to affect less than one person per million. Although the syndrome appears to be most common in countries that allow marriages between first cousins, there is no evidence as of 2021 that race or ethnicity by itself is a risk factor for CLSS.

Signs and symptoms

In addition to syndactyly, the typical symptoms of Cenani-Lenz syndrome include the following:

- absence of fingernails or toenails (anonychia; 90% of patients)
- syndactyly of toes as well as fingers (90%)
- frontal bossing (50%)
- fusion of the forearm bones (50%)
- abnormally widely spaced eyes (hypertelorism; 50%)
- underdevelopment of the forearm bones (50%)
- underdevelopment or abnormal location of the kidneys (7.5%)
- abnormally shaped ribs (7.5%)
- eye cataracts (7.5%)
- impaired hearing (7.5%)
- dislocation of the elbow (7.5%)
- reduced number of teeth (7.5%)
- underactive thyroid gland (7.5%)

Diagnosis

Ultrasound imaging during pregnancy, which will reveal the presence of syndactyly and malformations of the child's bones, can suggest the presence of CLSS. Genetic testing, however, is required to confirm the diagnosis. In the United States, laboratory testing is available for mutations of the *LRP4* and *APC* genes. These tests involve deletion or duplication analysis and sequencing of the entire coding region.

The diagnosis of CLSS after birth is usually made on the basis of the child's clinical appearance and confirmed by genetic testing. X-ray studies are performed in order to detect the precise location and extent of the malformations of the limbs and spine prior to corrective surgery.

Treatment and management

There is no cure for Cenani-Lenz syndrome. Treatment of the syndactyly requires surgery, which can be performed on infants as young as six months of age. In general, complex syndactyly should be treated as soon as possible to release the fingers and minimize permanent

QUESTIONS TO ASK YOUR DOCTOR

- My older child was born with complex syndactyly. Does that mean that he has Cenani-Lenz syndrome?
- There is a history of first-cousin marriage in the older generations on my father's side of the family. Should I be tested for mutations in the *LRP4* gene?
- How effective is surgical treatment for CLSS?
- Have you ever referred a patient to the Limb Study group in San Francisco for evaluation?

deformity of the hand and forearm. Children whose malformations are not corrected before they reach school age are at risk of losing function in the affected hands or feet, suffering developmental delays, and developing psychological problems, particularly if their facial features are deformed. The surgery should be performed by a specialist in hand surgery to lower the risk of postoperative complications and the recurrence of the syndactyly.

Children diagnosed with Cenani-Lenz syndrome (or any other genetic syndrome characterized by syndactyly) must be evaluated by the anesthesiologist prior to surgery to make sure that any spinal or rib cage deformities will not cause breathing difficulties under general anesthesia.

Physical therapy is necessary after surgery to maximize the child's use of the hands and ability to walk, even though the lower limbs are usually less seriously affected in CLSS than the hands and lower arms.

Research into CLSS and other genetic syndromes affecting the hands, feet, arms, and legs is carried out in the Limb Study conducted at the University of California, San Francisco. Persons with limb defects caused by genetic disorders who are interested in participating in the study can contact the University of California Department of Bioengineering and Therapeutic Sciences for more information.

Prognosis

The prognosis of children with Cenani-Lenz syndrome varies somewhat according to the severity of the syndactyly, oligodactyly, and other skeletal defects. It also varies according to whether the skeletal malformations are accompanied by kidney disorders, misshapen facial features, hypothyroidism, and dental abnormalities. At least one *LRP4* mutation has been identified as causing the prenatal death of the fetus.

Rebecca J. Frey, PhD

Central core disease

Definition

Central core disease (CCD) is an inherited muscle disorder that causes weakness of many of the voluntary muscles necessary for movement. The shoulders, hips, pelvis, and upper arms and legs are particularly affected.

Description

First described in 1956, central core disease is one of a group of muscle disorders, or myopathies, named for

certain abnormalities found in the muscle biopsies of people with the syndrome. In CCD, abnormal rounded areas, or cores, of certain muscle cells are present when viewed under the microscope. These core areas lack two particular organelles: mitochondria, which produce energy for the cell, and sarcoplasmic reticulum. The sarcoplasmic reticulum is involved with calcium release when muscle cells contract and calcium absorption when the cells relax. Changes in a particular protein on the muscle cells (the ryanodine receptor 1 protein) coupled with the absence of the sarcoplasmic reticulum causes the muscle cells to have an abnormal increase in the amount of calcium. The increased calcium leads to changes in muscle excitation and contraction leading to muscle weakness. These changes may be an abnormality or absence of this protein necessary for normal function of a muscle cell. The changes result from an altered gene (the *RYR1* gene).

Genetic profile

Central core disease is most often inherited as a dominant trait; that is, an alteration in one gene is enough to cause the condition. In dominant inheritance, an individual with CCD has a 50% chance of passing the disorder on to each child and an affected person usually has one affected parent. There are also occurrences of sporadic inheritance, which means that a gene alters spontaneously to cause the disorder in a person with no family history of the disease. Less often, CCD is inherited in a recessive pattern of inheritance, meaning that two copies of an altered gene are needed for a person to have the condition. In recessive inheritance, both parents of the affected person are unaffected carriers of an altered gene and the affected person usually has a low chance of having an affected child. In 1993, researchers identified the abnormal gene on chromosome 19q13 that leads to the disease. Many different changes in the gene have been documented in individuals with CCD. In general, it appears that the recessive form of CCD results in a more severe clinical presentation than the dominant form.

Demographics

The incidence of CCD is unknown. It is considered a rare disorder, with perhaps a higher incidence in Japan.

Signs and symptoms

Symptoms of central core disease are variable, even within the same family. Some individuals with the condition have an absence of noticeable features while others can be significantly more severely affected. Most often, the condition is not severe; however, the disease can be disabling. A mild general symmetric weakness of proximal muscles and hip displacement are key characteristics

KEY TERMS

Dominant trait—A genetic trait in which one copy of the gene is sufficient to yield an outward display of the trait; dominant genes mask the presence of recessive genes; dominant traits can be inherited from only one parent.

Malignant hyperthermia—A condition in which a person's body temperature may rise dangerously high in response to certain anesthetic drugs during surgery. If not recognized and treated quickly, this condition can lead to kidney failure and be fatal.

Mitochondria (singular, mitochondrion)—Organelles within the cell responsible for energy production.

Myopathy—Any abnormal condition or disease of the muscle.

Sarcoplasmic reticulum—A system of tubules surrounding muscle fibers that release calcium when muscle cells contract and absorb calcium when muscle cells relax.

Scoliosis—An abnormal curvature of the spine. In this condition, the curvature is usually side to side.

Sporadic inheritance—A situation in which a gene mutates spontaneously, or for the first time, to cause the disorder in a person with no family history of the disorder.

of the disease. Occasionally, the facial muscles show weakness. The disease often becomes noticeable in early childhood, when muscle cramps are present after exercising or performing other physical activities. Individuals with CCD have delayed motor skills, such as walking and jumping. Other features of the condition include scoliosis, muscle cramps, breathing difficulty, and, in some cases, malignant hyperthermia. In the more rare severe presentation, a newborn baby may have floppiness followed by periods of persistent muscle weakness, joint contractures, and breathing difficulty. Intelligence is not usually affected.

Diagnosis

The diagnosis of central core disease is made after several tests are completed. A neurological test involves checking an individual's coordination, tendon reflexes such as the knee-jerk reaction, walking ability, and the ability to rise from a sitting position. In addition, a muscle biopsy can be performed to look for the histopathological changes in the cell seen under the microscope. Molecular genetic testing is also available.

Sequencing of the DNA code that makes up the *RYR1* gene as well as looking for deletions or duplications in the gene detects over 90% of mutations. Once the mutation in a family has been identified, other relatives who may be at risk for the condition can also be tested for the condition, and prenatal diagnosis would be available for the family if desired.

Treatment and management

There is no cure for CCD. Treatment measures greatly depend on the severity of the individual's symptoms, especially the degree of muscle weakness that is involved. Treatment measures include surgical procedures, pain management, muscle stimulation therapy, and physical therapy. Individuals with CCD may need assistive devices like wheelchairs, respiratory support like a ventilator, or a feeding tube, and should inform physicians of the increased risk for malignant hyperthermia before any surgery so that an appropriate anesthetic can be used to prevent the condition. Individuals with CCD should wear a medical alert bracelet indicating the risk for malignant hyperthermia.

Prognosis

Although CCD is not a progressive illness, different people experience varying degrees of muscle weakness. Some children with CCD show mildly delayed motor milestones, then catch up and appear only slightly uncoordinated. Others have more severe delays, but also catch up somewhat and are able to walk and move about, although with more limitations. While most are able to walk independently, some children use braces for walking, and a few use wheelchairs.

Fortunately, the outlook for children with this disease is generally positive. Although children with central core disease start their life with some developmental delays, many improve as they get older and stay active throughout their lives. Lifespan is not usually shortened.

Related disorders

The clinical, microscopic, and genetic changes found in CCD can also be found in some other conditions. For instance, isolated cases of malignant hyperthermia (where no other clinical features are present) appear to be linked to the same gene on chromosome 19. Some other conditions such as multiminiore disease show similar muscle weakness and microscopic changes. In addition, other similar clinical conditions are known to be caused by changes in other genes. Therefore, an evaluation with a neurologist as well as a medical geneticist is recommended.

QUESTIONS TO ASK YOUR DOCTOR

- Please explain the bodily changes that take place in a person with central core disease.
- Are there symptoms by which central core disease can be recognized in infants and young children?
- What tests are available for confirming a diagnosis of central core disease?
- What is the prognosis for a child who has been diagnosed with central core disease?

Family support

There are several organizations that families with CCD can turn to for support. The Muscular Dystrophy Association (MDA) sponsors national events and provides information about various myopathies. They also raise money to fund research for cures, provide information to find local clinicians, and organize other family support events. The Muscular Dystrophy Campaign is a similar organization located in the United Kingdom. The Malignant Hyperthermia Association of the United States also assists families in finding information, medical help, and support.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL)

Definition

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, or CADASIL, is an inherited condition that can lead to strokes and impairments caused by thickened blood vessel walls in the brain.

Other names for cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, or CADASIL, include:

- Cerebral arteriopathy with subcortical infarcts and leukoencephalopathy
- Hereditary multi-infarct dementia
- Chronic familial vascular encephalopathy
- Lacunar dementia
- Agnogenic medial arteriopathy

Demographics

Age of onset varies, but symptoms of CADASIL normally do not appear until people are between the ages of 40 and 60 years old, although they can appear as early as age 20 in rare cases. A general age spread for the condition ranges from 30 to 60 years of age. CADASIL has been reported in people throughout the world. As of 2021, the prevalence of CADASIL was estimated to be between 2 and 4 persons per 100,000.

Description

Understanding CADASIL may be easier if its complex name—cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy—is considered word by word:

- *Cerebral* describes anything related to the brain.
- *Autosomal dominant* describes the type of genetic inheritance involved. It takes only one copy of the altered gene in each cell to cause CADASIL.

- *Arteriopathy* describes a disease of the body's arteries.
- *Subcortical* refers to a specific portion of the brain below the cerebral cortex. Nerve centers in this region control important functions such as reasoning and memory.
- *Infarcts* are areas of tissue in which the cells have died because of lost blood supply.
- *Leukoencephalopathy* refers to any disease that affects the brain's white matter, which contains nerve fibers.

CADASIL is then an inherited disorder caused by a mutation (pathogenic variant) in the *NOTCH3* gene. The gene provides instructions for producing a receptor protein of the same name. This protein is important for normal function of certain cells. Through a complex process at the molecular level, the receptors send signals to the nuclei of cells that normally activate genes within the smooth muscle cells of veins. *NOTCH3* gene mutations cause the protein to accumulate abnormally and affect the function and survival of cells, mainly in the brain's vasculature (blood veins) blood vessels and some tissue arteries. Eventually, the cells self-destruct.

The damaged blood vessels eventually cause a reduction or total loss of blood flow to the affected areas. Sometimes, migraines and other symptoms are the first indications of CADASIL, but eventually the blood vessel damage leads to stroke. As many as 85% of people with symptoms of CADASIL have strokes or transient ischemic attacks (strokes that come and go quickly). Most people with CADASIL have repeated strokes, which eventually lead to other problems, such as dementia.

The only known risk factor for CADASIL is inheritance of the genetic mutation responsible for the disorder. As of 2021, research had not shown a link between risk behaviors such as smoking, high blood pressure, or high cholesterol and the onset of CADASIL. The only link seems to be between current smoking in an adult who has CADASIL and likelihood of stroke.

Genetic profile

CADASIL is an autosomal dominant disease. It develops due to the presence of a mutated gene on one of the two copies of the *NOTCH3* gene that each individual has. One mutated copy of the *NOTCH3* gene is all that is needed for expression of the disease. All humans have two copies of the *NOTCH3* gene but a single mutated copy of the *NOTCH3* gene can override a normal copy of the gene. As a result, CADASIL is a disease that is inherited from an affected parent and is seen in multiple generations of a family. Each child of a parent who carries the mutation has a 50% chance of having CADASIL. For the most part, there is little

KEY TERMS

Dementia—A condition that affects memory and other cognitive abilities and that is usually progressive. Alzheimer's disease is a common form of dementia.

Migraine—A condition marked by severe headaches, often on one side of the head and accompanied by nausea, light and sound sensitivity, and other symptoms. Migraines are believed to involve the nerves and blood vessels of parts of the brain and head.

Nuclei—Plural for nucleus, a special part of the cell that is essential for cell function.

Phenotype—Observable characteristics that result from presentation of a gene. In the case of CADASIL, this includes the observable signs, symptoms, and characteristics of the disease in individuals.

Transient ischemic attack (TIA)—A neurologic dysfunction that comes and goes quickly and is similar to a stroke.

variation among the phenotypes (external characteristics of this genetic disorder), but a few have been observed. For example, some people may have strokes in their 20s and others may not have strokes until they are in their 60s.

The symptoms of CADASIL generally do not appear until mid-life and include the following:

- Stroke or transient ischemic attacks before age 60. Often multiple strokes occur.
- Migraine with aura. A migraine is a headache that involves the nerves and blood vessels in the head. An aura is an abnormal sensation, usually visual, that signals the headache is going to occur.
- Cognitive problems regarding memory and attention. These problems usually worsen with the disease and memory loss is progressive.
- Psychiatric or mood disorders, including depression or abnormal behavior.

Other symptoms may occur but are reported less frequently, including the following:

- Epileptic seizures
- Dementia
- Problems with vision
- Paralysis on one side of the body.

Not everyone who has CADASIL will have every symptom. Some symptoms are less common. For

example, a study found that some women with CADASIL are more likely to have a stroke during pregnancy or soon after childbirth, especially if they are over age 30. Migraines that begin later in life than is typical and strokes that occur earlier than is typical, as well as recurring strokes, are the most common symptoms of CADASIL.

Signs and symptoms

The only known cause of CADASIL is the inherited genetic mutation in the *NOTCH3* gene.

Diagnosis

There is no set clinical guideline for diagnosing CADASIL. The most common way to diagnose CADASIL is by taking a biopsy (sample of muscle or skin tissue) that is viewed under a special microscope. The granular material, called granular osmiophilic material (GOM), is deposited in smooth muscle cells. Pathologists can view the sample and detect GOM accumulation of *NOTCH3* with the help of a technique called electron microscopy. The method is not always exact, as it depends on the accuracy of the sample and the skill of the pathologist. Therefore, a negative result from the biopsy does not necessarily clear the patient of having CADASIL.

If CADASIL is suspected based on symptoms, family history, or biopsy results, DNA testing of the *NOTCH3* gene can confirm the diagnosis. DNA testing is done primarily by DNA sequencing of the *NOTCH3* gene. DNA sequencing is the molecular determination of the precise sequence of nucleotides in a sample of DNA. By looking at the coding regions (exons) of the *NOTCH3* gene and the junctions between these coding regions, mutations or changes in the sequence of nucleotides can be found. If no mutations are detected, then deletion/duplication testing which looks for copy number variants is performed. Using these two testing approaches, it is estimated that greater than 96% of the mutations responsible for CADASIL will be detected.

Procedures

Magnetic resonance imaging (MRI) can be used to look for white matter changes in the brain that are characteristic of CADASIL. A radiologist is a physician who is trained to interpret MRI exams; he or she also will look for lesions where the white matter and gray matter of the brain meet. There may be other causes for these changes, so reviewing the family medical history helps in diagnosis. The family medical history would look for

QUESTIONS TO ASK YOUR DOCTOR

- What can I do to minimize my risk of stroke?
- How can I find out about clinical trials that exist for CADASIL treatment or management?
- If my family has a history of CADASIL, how can I determine the likelihood of passing CADASIL to my children?
- How can I delay the onset of dementia?
- Is there a support group in this community I can turn to?

occurrences of CADASIL, as well as possible CADASIL symptoms.

Tests

There are genetic tests available that can confirm CADASIL by finding the *NOTCH3* mutation in DNA coding regions. Genetic tests to predict whether a person has CADASIL seldom are performed, but they might be used to confirm a diagnosis. The genetic tests are reliable, correctly diagnosing CADASIL in about 96% of cases.

Treatment and management

There is no known treatment that can halt or slow CADASIL. Various treatments can be used to manage the symptoms of the disorder.

Migraine management

Many medications can help manage migraines. A neurologist may prescribe prophylactic (preventive) medications such as antiseizure drugs to help control the frequency and severity of migraine attacks. Medications also are available to help manage the pain and other symptoms of migraine attacks once they occur.

Stroke care

Some neurologists prescribe salicylates to help prevent strokes. Use of aspirin therapy also may help prevent strokes.

Supportive care

Patients with CADASIL may receive a number of supportive care services. For example, services may be offered to help deal with the effects of stroke and cognitive decline or dementia. Patients may receive counseling or other therapies.

Prevention

As of 2021, there was no way to prevent CADASIL or its onset in those who are born with the mutation. Some steps can be taken to prevent the number of strokes or delay onset of stroke. Studies have shown that smoking increases stroke attacks in people who have CADASIL, so people with the disease are advised to quit smoking. Patients with CADASIL also may be advised not to take anticoagulants (medicines that thin the blood) because they may increase the risk of accidents in the brain's vessels. They also may be advised to avoid angiography procedures for the same reason.

Prognosis

The disease progresses slowly, but most people with CADASIL have severe cognitive problems and dementia by the time they reach age 65. The multiple strokes they experience may lead to inability to walk or care for themselves. Some clinicians have suggested that people with hypertension and other heart problems have a worse prognosis. As of 2021, research only seemed to support that smoking leads to more rapid onset of stroke.

Cerebral palsy

Definition

Cerebral palsy (CP) is the term used for a group of nonprogressive disorders of movement and posture caused by abnormal development of (or damage to) motor control centers of the brain. CP is caused by events before, during, or after birth. The abnormalities of muscle control that define CP are often accompanied by other neurological and physical abnormalities.

Description

CP is not a specific diagnosis. It is more accurately considered a description of a broad but defined group of neurological and physical problems.

Voluntary movement (walking, grasping, chewing, for example) is primarily accomplished using muscles that are attached to bones, known as the skeletal muscles. Control of the skeletal muscles originates in the cerebral cortex, the largest portion of the brain. *Palsy* means paralysis, but may also be used to describe uncontrolled muscle movement or tension (hypertonia). Therefore, cerebral palsy encompasses any disorder of abnormal movement and paralysis caused by abnormal function of the cerebral cortex. In truth, however, CP does not include conditions due to progressive disease or degeneration of the brain. For this reason, CP is also referred to as static (nonprogressive) encephalopathy (disease of the brain). Also excluded from CP are any disorders of muscle control that arise in the muscles themselves and/or in the peripheral nervous system (nerves outside the brain and spinal cord).

The symptoms of CP and their severity are quite variable. Those with CP may have only minor difficulty with fine motor skills, such as grasping and manipulating items with their hands. A severe form of CP could involve significant muscle problems in all four limbs, mental disability, seizures, and difficulties with vision, speech, and hearing.

Muscles that receive abnormal messages from the brain may be constantly contracted and tight (spastic), exhibit involuntary writhing movements (athetosis), or have difficulty with voluntary movement (dyskinesia). There can also be a lack of balance and coordination with unsteady movements (ataxia). A combination of any of these problems may also occur. Spastic CP and mixed CP constitute the majority of cases. Effects on the muscles can range from mild weakness or partial paralysis (*paresis*) to complete loss of voluntary control of a muscle or group of muscles (*plegia*). CP is also designated by the number of limbs affected. For instance, having

Colored magnetic resonance imaging (MRI) scan of an axial (horizontal) section through the head of a child with cerebral palsy. The front of the head is at top. A right frontal porencephalic cyst can be seen (dark red), which is an abnormal cyst or cavity filled with cerebrospinal fluid (CSF). In this case it has resulted in left-sided weakness of the child. Cerebral palsy is a developmental abnormality caused by damage to the brain during late pregnancy, childbirth, or early childhood. (Simon Fraser/Science Source)

affected muscles in one limb is monoplegia; having affected muscles in both arms or both legs is diplegia; having affected muscles in both limbs on one side of the body is hemiplegia; and having affected muscles in all four limbs is quadriplegia. Muscles of the trunk, neck, and head may be affected as well.

CP can be caused by a number of different mechanisms at various times—from several weeks after conception through birth, and into early childhood. For many years, it was accepted that most cases of CP were due to brain injuries received during a traumatic birth, known as birth asphyxia. However, extensive research in the 1980s showed that only 5%–10% of CP can be attributed to birth trauma. Other possible causes include abnormal development of the brain, prenatal factors that directly or indirectly damage neurons in the developing brain, premature birth, and brain injuries that occur in the first few years of life.

Genetic profile

As noted, CP has many causes, making a discussion of the genetics of CP complicated. About 2% of all cases

of CP were thought to result from genetic mutations as of 2021. In addition, a number of hereditary or genetic syndromes have signs and symptoms similar to CP, but they usually also have associated problems that are not typical of CP. Put another way, some hereditary conditions mimic CP. Isolated CP, meaning CP that is not a part of some other syndrome or disorder, is usually not inherited.

It might be possible to group the causes of CP into those that are genetic and those that are non-genetic, but most would fall somewhere in between. Grouping the causes according to the time of injury is preferable to a genetic and nongenetic classification. The time-related classification of causes would be those that occur during pregnancy (prenatal), those that happen around the time of birth (perinatal), and those that occur after birth (post-natal). Classifying CP related to premature birth and multiple-birth pregnancies (e.g., twins or triplets) is somewhat different and considered separately.

Prenatal causes

Although much has been learned about human embryology in the last several decades, a great deal remains unknown. Studying prenatal human development is difficult because the embryo and fetus develop in a closed environment—the mother’s womb. However, the relatively recent development of a number of prenatal tests has opened a window on the process. Add to that more accurate and complete evaluations of newborns, especially those with problems, and a clearer picture of what can go wrong before birth is possible.

The complicated process of brain development before birth is susceptible to many chance errors that can result in abnormalities of varying degrees of severity. Some of these errors will result in structural anomalies of the brain, while others may cause undetectable but significant abnormalities in the “wiring” of the cerebral cortex. An abnormality in structure or function is sometimes hereditary but is most often due to chance or a cause unknown at this time. Recognizing the degree to which genetic factors play a role in a particular brain abnormality depends on the type of anomaly and the form of CP it causes.

GENETIC. As noted above, genetic mutations are thought to account for about 2% of all cases of CP. As of 2015, two genes had been identified that are associated with specific subtypes of cerebral palsy. Both genetic mutations are inherited in an autosomal recessive pattern. In 2004, a mutation in the *GAD1* gene on chromosome 2 at 2q31 was identified as the cause of a form of spastic cerebral palsy. The *GAD1* gene codes for an enzyme called glutamate decarboxylate-1, which is important in

neurotransmission. Mutations in this gene have been implicated in insulin-dependent (type 1) diabetes and bipolar disorder as well as CP.

The other gene associated with CP is the *CPAT1* gene on chromosome 9 at 9p12-q12. This gene, which was incompletely understood as of 2021, has been linked to ataxic cerebral palsy, which accounts for 5%–10% of all forms of CP. About 50% of cases of ataxic CP are thought to be inherited as an autosomal recessive trait.

It is likely that more candidate genes associated with CP will be discovered or confirmed in the near future. A group of researchers at the University of California, San Francisco, reported in 2013 that a single nucleotide polymorphism (SNP) in the *IL6* gene increases a child's risk of CP. This gene regulates the levels of the IL-6 protein in amniotic fluid and within brain lesions. An international team of American, Australian, and Dutch geneticists reported in early 2015 that whole-exome sequencing of 183 cases of CP indicated that as many as 14% of cases may have a genetic component. The team's findings underscore the complexity of the genetic contribution to CP.

INFECTIOUS. Several maternal-fetal infections are known to increase the risk of CP, including rubella (German measles, now rare in the United States), cytomegalovirus (CMV), and toxoplasmosis. Each of these infections is considered a risk to the fetus only if the mother contracts it for the first time during that pregnancy. Even in those cases, though, most babies will be born normal. Most women are immune to all three infections by the time they reach childbearing age, but a woman's immune status can be determined using the TORCH (toxoplasmosis, rubella, cytomegalovirus, and herpes) test before or during pregnancy.

CARDIOVASCULAR. Just as a stroke can cause neurologic damage in an adult, so too can this type of event occur in the fetus. A burst blood vessel in the brain followed by uncontrolled bleeding (coagulopathy), known as intracerebral hemorrhage, could cause a fetal stroke, as could a cerebral blood vessel obstructed by a clot (embolism). Infants who later develop CP, along with their mothers, are more likely than other mother-infant pairs to test positive for factors that put them at increased risk of bleeding episodes or blood clots. Some coagulation disorders are strictly hereditary, but most have a more complicated origin.

ENVIRONMENTAL. A teratogen is any substance to which a woman is exposed that has the potential to harm the embryo or fetus. Links between a drug or other chemical exposure during pregnancy and an increased risk of CP are difficult to prove. However, any substance that might affect fetal brain development directly or indirectly

could increase the risk of CP. Furthermore, any substance that increases the risk of premature delivery and low birth weight, such as alcohol, tobacco, or cocaine, may indirectly increase the risk of CP.

The fetus receives all nutrients and oxygen from blood circulating through the placenta. Therefore, anything that interferes with normal placental function may adversely affect the brain development of the fetus or may increase the risk of premature delivery. Structural abnormalities of the placenta, premature detachment of the placenta from the uterine wall (abruptio placentae), and placental infections (chorioamnionitis) are thought to pose some risk of CP.

IMMUNOLOGIC. Certain conditions in the mother during pregnancy may pose a risk to fetal development leading to CP. Women with autoimmune antithyroid or antiphospholipid (APA) antibodies are at slightly increased risk of CP in their children. A potentially important clue points toward high levels of cytokines in the maternal and fetal circulation as a possible risk for

Young boy with cerebral palsy using a walker. (Jaren Jai Wicklund/Shutterstock)

CP. Cytokines are proteins associated with inflammation, such as inflammation caused by infection or autoimmune disorders. These cytokines may be toxic to neurons in the fetal brain. More research is needed to determine the exact relationship, if any, between high levels of cytokines in pregnancy and CP. A woman has some risk of developing the same complications in more than one pregnancy, slightly increasing the risk of bearing more than one child with CP.

Serious physical trauma to the mother during pregnancy may result in direct trauma to the fetus as well. Furthermore, injuries to the mother may compromise the availability of nutrients and oxygen to the developing fetal brain.

Perinatal causes

Birth asphyxia significant enough to result in CP is now uncommon in developed countries. A tight nuchal cord (umbilical cord around the baby's neck) and prolapsed cord (cord delivered before the baby) are possible causes of birth asphyxia, as are bleeding and other complications associated with placental abruption and placenta previa (placenta lying over the cervix).

Infection in the mother is sometimes not passed to the fetus through the placenta, but is transmitted to the baby during delivery. Some examples include chlamydia, gonorrhea, CMV, human papilloma virus (HPV), and Group B streptococci (GBS). Any such infection that results in serious illness in the newborn has the potential to produce some neurological damage.

Postnatal causes

The remaining 15% of CP is due to neurological injury sustained after birth. CP that has a postnatal cause is sometimes referred to as acquired CP, but this name is accurate only for those cases caused by infection or trauma.

Incompatibility between the Rh blood types of mother and child (mother Rh negative, baby Rh positive) can result in severe anemia in the baby (erythroblastosis fetalis). This incompatibility may lead to other complications, including severe jaundice, which can cause CP. Rh disease in the newborn is now rare in developed countries due to routine screening of maternal blood type and treatment of at-risk pregnancies. The routine effective treatment of jaundice due to other causes has also made it an infrequent cause of CP in developed countries. Rh blood type poses a risk for recurrence of Rh disease if treatment is not provided.

Such serious infections that affect the brain directly as meningitis and encephalitis may cause irreversible damage to the brain, leading to CP. A seizure disorder

early in life may cause CP, or may be the product of a hidden problem that causes CP in addition to seizures. Unexplained (idiopathic) seizures are hereditary in only a small percentage of cases. Although rare in infants born healthy at or near term, intracerebral hemorrhage and brain embolism, like fetal stroke, are sometimes genetic.

Physical trauma to an infant or child resulting in brain injury, such as from abuse, accidents, or near drowning/suffocation, may cause CP. Likewise, ingestion of such toxic substances as lead, mercury, poisons, or certain chemicals may cause neurological damage. Accidental overdose of certain medications may also cause similar damage to the central nervous system.

Prematurity and multiple-birth pregnancy

Advances in the medical care of premature infants in the last 20 years have dramatically increased the rate of survival of these fragile newborns. However, as gestational age at delivery and birth weight of a baby decrease, the risk of CP increases dramatically. A term pregnancy is delivered at 37–41 weeks' gestation. The risk of CP in a preterm infant (32–37 weeks) is increased about fivefold over the risk for an infant born at term. Survivors of extremely preterm births (less than 28 weeks) face as much as a fiftyfold increase in risk. About 50% of all cases of CP now being diagnosed are in children who were born prematurely.

Two factors are involved in the risk of CP associated with prematurity. First, premature babies are at higher risk of CP-associated medical complications, such as intracerebral hemorrhage, infection, and difficulty in breathing. Second, the onset of premature labor may be induced in part by complications that have already caused neurologic damage in the fetus. A combination of both factors almost certainly plays a role in a number of cases of CP. The tendency toward premature delivery tends to run in families, but the genetic mechanisms are far from clear.

An increase in multiple birth pregnancies in recent years, especially in the United States, is attributed to the increased use of fertility drugs. As the number of fetuses in a pregnancy increases, the risks of abnormal development and premature delivery also increase. Children from twin pregnancies have four times the risk of developing CP as those from singleton pregnancies, owing to the fact that more twin pregnancies are delivered prematurely. The risk of CP in a triplet is up to 18 times greater. Furthermore, recent evidence suggests that a baby from a pregnancy in which its twin died before birth is at increased risk of CP.

KEY TERMS

Asphyxia—Lack of oxygen. In the case of cerebral palsy, lack of oxygen to the brain.

Ataxia—A deficiency of muscular coordination, especially when voluntary movements are attempted, such as grasping or walking.

Athetosis—A condition marked by slow, writhing, involuntary muscle movements.

Cerebral palsy—Movement disability resulting from nonprogressive brain damage.

Coagulopathy—A disorder in which blood is either too slow or too quick to coagulate (clot).

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

Cytokine—A protein associated with inflammation that, at high levels, may be toxic to nerve cells in the developing brain.

Diplegia—Paralysis affecting like parts on both sides of the body, such as both arms or both legs.

Dorsal rhizotomy—A surgical procedure that cuts nerve roots to reduce spasticity in affected muscles.

Dyskinesia—Impaired ability to make voluntary movements.

Hemiplegia—Paralysis of one side of the body.

Hypotonia—Reduced or diminished muscle tone.

Quadriplegia—Paralysis of all four limbs.

Serial casting—A series of casts designed to gradually move a limb into a more functional position.

Single nucleotide polymorphism (SNP)—A DNA sequence variation in which a single nucleotide in the genome differs between two individuals of the same species or between two paired chromosomes. SNPs affect individuals' susceptibility to diseases.

Spastic—Referring to a condition in which the muscles are rigid, posture may be abnormal, and fine motor control is impaired.

Spasticity—Increased muscle tone, or stiffness, which leads to uncontrolled, awkward movements.

Static encephalopathy—A disease of the brain that does not get better or worse.

Tenotomy—A surgical procedure that cuts the tendon of a contracted muscle to allow lengthening.

Demographics

As of 2019, over 760,000 people in the United States were living with CP. For every 1,000 babies born in the United States, approximately 3 will be diagnosed with some type of CP by the time they are 8 years old. This results in 10,000 babies born with CP every year. Thus, CP is the most widespread cause of childhood disability. It is more common among boys than girls, and more common among African American children than white children, with Asians having the lowest rates. In addition, around 1,200–1,500 preschool-age children are recognized each year to have CP.

Signs and symptoms

By definition, the defect in cerebral function causing CP is nonprogressive. However, the symptoms of CP often change over time. Most of the symptoms of CP relate in some way to the aberrant control of muscles. To review, CP is categorized first by the type of movement/postural disturbance(s) present; then, by a description of which limbs are affected; and finally, by the severity of motor impairment. For example, spastic diplegia refers to continuously tight muscles that have no voluntary control in both legs, while athetoid quadriplegia describes uncontrolled

writhing movements and muscle weakness in all four limbs. These three-part descriptions are helpful in providing a general picture, but cannot give a complete description of any one person with CP. In addition, the various forms of CP do not occur with equal frequency—spastic diplegia is seen in more individuals than is athetoid quadriplegia. CP can also be loosely categorized as mild, moderate, or severe. However, these are very subjective terms with no firm boundaries among them.

A muscle that is tensed and contracted is hypertonic, while excessively loose muscles are hypotonic. Spastic, hypertonic muscles can cause serious orthopedic problems, including scoliosis (spine curvature), hip dislocation, or contractures. A contracture is shortening of a muscle, aided sometimes by a weak opposing force from a neighboring muscle. It may become permanent, or “fixed,” without some intervention. Fixed contractures may cause postural abnormalities in the affected limbs. Clenched fists and contracted feet (equinus or equinovarus) are common in people with CP. Spasticity in the thighs causes them to turn in and cross at the knees, resulting in an unusual method of walking known as a scissors gait. Any of the joints in the limbs may be stiff (immobilized) due to spasticity of the attached muscles.

Athetosis and dyskinesia often occur with spasticity, but do not often occur alone. The same is true of ataxia. It is important to remember that “mild CP” or “severe CP” refers not only to the number of symptoms present, but also to the level of involvement of any particular class of symptoms.

Mechanisms that can cause CP are not always restricted to motor-control areas of the brain. Other neurological symptoms may include:

- mental and learning disabilities (about 50%)
- behavioral disorders
- seizure disorders (about 28%)
- visual impairment (about 42%)
- hearing loss
- speech impairment (dysarthria; about 58%)
- abnormalities of sensation and perception

These problems may have a greater impact on a child’s life than the physical impairments of CP, although not all children with CP are affected by other problems. Many infants and children with CP have growth impairment. About one-third of individuals with CP have moderate to severe mental disability, about one-third have mild mental disability, and the remainder have normal intelligence.

Diagnosis

Diagnosis of CP is based on the child’s clinical presentation rather than laboratory or imaging tests. The signs of CP are not usually noticeable at birth. Children normally progress through a predictable set of developmental milestones through the first 18 months of life. Children with CP, however, tend to develop these skills more slowly because of their motor impairments. Therefore, delays in reaching milestones are usually the first symptoms of CP. Babies with more severe cases of CP are normally diagnosed earlier than others.

Selected developmental milestones and the ages for normally acquiring them are given below. If a child does not acquire the skill by the age shown in parentheses, there is some cause for concern.

- Sits well unsupported—6 months (8–10 months)
- Babbles—6 months (8 months)
- Crawls—9 months (12 months)
- Finger-feeds, holds bottle—9 months (12 months)
- Walks alone—12 months (15–18 months)
- Uses one or two words other than dada/mama—12 months (15 months)
- Walks up and down steps—24 months (24–36 months)

QUESTIONS TO ASK YOUR DOCTOR

- How certain is your diagnosis of cerebral palsy for my child?
- What confirmatory tests can be performed to increase the reliability of this diagnosis?
- What type of cerebral palsy does my child have?
- Given your diagnosis, what is the long-term prognosis for my child?
- What types of treatment and/or care are available for a child with cerebral palsy?
- Does my child have one of the rare forms of CP related to gene mutations?
- Can you recommend support groups for CP patients and their family members in our area?

- Turns pages in books; removes shoes and socks—24 months (30 months)

Children do not consistently favor one hand over the other before 12 to 18 months, and doing so may be a sign that the child has difficulty using the other hand. This same preference for one side of the body may show up as asymmetric crawling, or later on, favoring one leg while climbing stairs.

Children normally progress at somewhat different rates; slow beginning accomplishment is often followed by normal development. Other causes for developmental delay—some benign, some serious—should be excluded before considering CP as the answer. CP is nonprogressive, so continued loss of previously acquired milestones indicates that CP is not the cause of the problem.

There is no single diagnostic test for CP as of 2015, but certain factors increase suspicion. The Apgar score measures a baby’s condition immediately after birth. Babies who have low Apgar scores are at increased risk of CP. Presence of abnormal muscle tone or movements may indicate CP, as may the persistence of infantile reflexes. Imaging of the brain using ultrasound, x-rays, MRI, and/or CT scans may reveal a structural anomaly. Evidence of some brain lesions associated with CP include scarring, cysts, expansion of the cerebral ventricles (hydrocephalus), periventricular leukomalacia (an abnormality of the area surrounding the ventricles), areas of dead tissue (necrosis), and signs of an intracerebral hemorrhage or blood clot. Blood and urine biochemical tests, as well as genetic tests, may be used to rule out other possible causes, including muscle and

peripheral nerve diseases, mitochondrial and metabolic diseases, and other inherited disorders. Evaluations by a pediatric developmental specialist and a geneticist may be beneficial.

Treatment and management

Cerebral palsy cannot be cured, but many of the disabilities it causes can be managed through planning and timely care. Treatment for a child with CP depends on the severity, nature, and location of the primary muscular symptoms, as well as any associated problems that might be present. Optimal care of a child with mild CP may involve regular interaction with only a physical therapist and occupational therapist. Care for a more severely affected child may include visits to multiple medical specialists throughout life. With proper treatment and an effective plan, most people with CP can lead productive, happy lives.

Importance of early intervention

Data of limited quantity and quality suggest benefit from early interventions, with medium effect size for motor development. If implemented as part of an early intervention program while the child is still developing, certain therapies for CP can lessen the impact of impairment and minimize the child's potential for developing associated conditions.

Therapy

Spasticity, muscle weakness, coordination, ataxia, and scoliosis are all significant impairments that affect the posture and mobility of a person with CP. Physical and occupational therapists work with the patient and the family to maximize the ability to move affected limbs, develop normal motor patterns, and maintain posture. Assistive equipment such as wheelchairs, walkers, shoe inserts, crutches, and braces is often required. A speech therapist and such high-tech aids as computer-controlled communication devices can make a tremendous difference in the life of someone who has speech impairments.

Medications

Before fixed contractures develop, such muscle relaxants as diazepam (Valium), dantrolene (Dantrium), and baclofen (Lioresal) may be prescribed. Botulinum toxin (Botox), a newer and highly effective treatment, is injected directly into the affected muscles. Alcohol or phenol injections into the nerves controlling the muscle are other options. Multiple medications are available to control seizures. Athetosis can be treated using medications such as trihexyphenidyl HCl (Artane) and benzotropine (Cogentin).

Surgery

Fixed contractures are usually treated with either serial casting or surgery. The most commonly used surgical procedures are tenotomy, tendon transfer, and dorsal rhizotomy. In tenotomy, the tendons of the affected muscle are cut and the limb is cast in a more normal position while the tendon regrows. Alternatively, tendon transfer involves cutting and reattaching a tendon at a different point on the bone to enhance the length and function of the muscle. A neurosurgeon performing dorsal rhizotomy carefully cuts selected nerve roots in the spinal cord to prevent them from stimulating the spastic muscles. Neurosurgical procedures in the brain, such as implanting tiny electrodes directly into the cerebellum or cutting a portion of the hypothalamus, have very specific uses and have had mixed results.

Education

Parents of a child newly diagnosed with CP are not likely to have the necessary expertise to coordinate the full range of care their child will need. Although knowledgeable and caring medical professionals are indispensable for developing a care plan, a potentially more important source of information and advice is other parents who have dealt with the same set of difficulties. Support groups for parents of children with CP can be significantly effective sources of both practical advice and emotional support. Many cities have support groups that can be located through the United Cerebral Palsy Association. Furthermore, most large medical centers have special multidisciplinary clinics for children with developmental disorders.

Clinical trials

Many clinical trials for the treatment of cerebral palsy are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2021, the NIH reported 920 recruiting, ongoing, or recently completed studies. Current clinical trials include studies of robotic wheelchairs and other robotic assistive devices for children with CP. Other studies include investigational medications, and the use of hyperbaric oxygen therapy. Experimental treatments include functional electrical stimulation (FES) as a form of treatment for CP, and prenatal administration of magnesium sulfate as a preventive measure.

Clinical trial information is constantly updated by NIH. The most recent information on CP trials can be found at: <https://clinicaltrials.gov/ct2/home>

Prognosis

Cerebral palsy can affect every stage of maturation from childhood through adolescence, and into adulthood. At each stage, those with CP, along with their caregivers,

must strive to achieve and maintain the fullest range of experiences and education consistent with their abilities. The advice and intervention of various professionals remains crucial for many people with CP. Although CP itself is not considered a terminal disorder, it can affect a person's lifespan by increasing the risk of certain medical problems like osteoarthritis, depression, chronic pain, high blood pressure, and urinary incontinence. People with mild cerebral palsy may have near-normal lifespans, but the lifespan of those with more severe forms may be shortened. However, over 90% of infants with CP survive into adulthood.

The cause of most cases of CP remains unknown, but it has become clear in recent years that birth difficulties are not to blame in most cases. Rather, developmental problems before birth, usually unknown and generally undiagnosable, are responsible for most cases. The rate of survival for preterm infants has leveled off in recent years. Furthermore, methods to improve the long-term health of these at-risk babies are now being sought. Current research is also focusing on the possible benefits of recognizing and treating coagulopathies and inflammatory disorders in the prenatal and perinatal periods. The use of magnesium sulfate in pregnant women with preeclampsia or threatened preterm delivery may reduce the risk of CP in very preterm infants. Finally, the risk of CP can be decreased through good maternal nutrition, avoidance of drugs and alcohol during pregnancy, and prevention or prompt treatment of infections.

Channelopathies

Definition

Channelopathies are inherited diseases caused by defects in cell proteins called ion channels. These diseases appear as episodes of epilepsy, headache disorders, and movement disorders (dyskinesias).

Channelopathies include a wide range of neurologic diseases, including periodic paralysis, congenital myasthenic syndromes, malignant hyperthermia, a form of Charcot-Marie-Tooth disease, cystic fibrosis, and long Q-T syndrome.

Description

Channelopathies are a diverse group of disorders resulting from the dysfunction of proteins, called ion channels, that transport materials across the cell membrane. Ion channels are found in every cell of the body. These cells, including nerve and muscle cells, are surrounded by thin coverings called membranes. Embedded in these membranes are a large and varied set of proteins that control the movement of materials across the membrane, in and out of the cell. One major type of material that crosses through such proteins includes ions. The proteins that transport these proteins are called ion channels.

Ions perform many different functions in cells. In neurons (nerve cells), they help transmit the electrical messages that allow neurons to communicate not only with each other, but also with muscle cells. In muscle cells, they allow the muscle to contract. When the ion channels are defective, these activities may be disrupted.

When these ion channels malfunction, many diseases throughout the body may occur. Among conditions caused by channelopathies are:

- Diseases of the nervous system: Generalized epilepsy with febrile seizures, familial hemiplegic migraine, episodic ataxia, and hyperkalemic and hypokalemic periodic paralysis.
- Diseases of the cardiovascular system: Long QT syndrome, short QT syndrome, Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia.
- Diseases of the respiratory system: Cystic fibrosis.
- Diseases of the endocrine system: Neonatal diabetes mellitus, familial hyperinsulinemic hypoglycemia, thyrotoxic hypokalemic periodic paralysis, and familial hyperaldosteronism.
- Diseases of the urinary system: Bartter syndrome, nephrogenic diabetes insipidus, autosomal-dominant polycystic kidney disease, and hypomagnesemia with secondary hypocalcemia.

- Diseases of the immune system: Myasthenia gravis, neuromyelitis optica, Isaac syndrome, and anti-NMDA (N-methyl-D-aspartate) receptor encephalitis.

Inheritance

The proteins responsible for channelopathies are made by genes, and defects in these genes cause diseases. Genes are inherited from both parents. Many unique gene mutations have been identified that cause ion channelopathies. These mutations are specific to the genes that relate to the affected body part of the system. If a disease follows a recessive inheritance pattern, two defective copies of a gene are needed in order for a person to develop the disease. Two parents, each of whom carry one defective copy, have a 25% chance with each pregnancy of having a child with the disease.

If a disease follows a dominant inheritance pattern, only one defective copy of the gene is needed in order to develop the disease. When only one parent carries the disease gene (and likely has the disease as well), there is a 50% chance with each pregnancy of having a child with the disease.

Types of channelopathies

Periodic paralysis

A person with periodic paralysis experiences sudden onset of weakness, which gradually subsides, only to return again later. Two forms of periodic paralysis exist, termed “hyperkalemic,” referring to the excessively high levels of potassium in the blood that can trigger attacks, and “hypokalemic,” in which excessively low levels of potassium are the culprit. Each is caused by different genetic mutations of a potassium ion channel. Both exhibit the dominant inheritance pattern. Onset is usually in childhood for the hyperkalemic form, and childhood to adulthood for the hypokalemic form. Dietary restrictions can reduce the frequency of attacks of both forms, with a high-carbohydrate, low-potassium diet for the hyperkalemic form, and a low-carbohydrate, high-potassium diet for the hypokalemic form.

Congenital myasthenic syndromes

Congenital myasthenic syndromes are a group of related disorders caused by inherited defects in the acetylcholine receptor. This protein sits on the surface of muscle cells. When a nearby neuron releases the chemical acetylcholine, it binds to the receptor, causing the muscle to contract. Defects cause myasthenia (“muscle weakness”) and fatigue and may be life threatening in some individuals. Most forms display the recessive inheritance pattern. Mutations in the *CHRNE* gene are responsible for

more than half of all cases. A large number of cases are also caused by mutations in the *RAPSN*, *CHAT*, *COLQ*, and *DOK7* genes.

Malignant hyperthermia

Malignant hyperthermia is caused by mutations of the *CACNA1S* and *RYR1* genes. These genes contain instructions for creating the membrane protein inside the muscle cell, called the ryanodine receptor, which controls calcium ion movement within the muscle and a different muscle protein controlling calcium. Malignant hyperthermia is usually triggered by exposure to certain kinds of anesthetics or muscle relaxants. It causes a dangerous increase in the rate of activity within the muscle and a sharp rise in temperature, leading to a variety of threats. These threats may include severe damage to muscle cells, heart malfunction, swelling of tissues (including the brain), and death. Scientists have identified at least six other genetic mutations that may cause this condition.

Charcot-Marie-Tooth disease

Charcot-Marie-Tooth disease is a group of progressive disorders that affect the nerves linking the brain and spinal cord to muscles and sensory cells. These nerves detect sensations such as touch, pain, heat, and sound. Charcot-Marie-Tooth disease can result in loss of sensation and wasting of muscles in the feet, legs, and hands. Charcot-Marie-Tooth disease is caused by mutations in many different genes. These genes provide instructions for making proteins that are involved in the function of nerves in the feet, legs, and hands. It is suspected that the gene mutations that cause Charcot-Marie-Tooth disease likely impair axons, which transmit nerve impulses, or affect the specialized cells that produce myelin. As a result, these nerve cells slowly lose the ability to stimulate the muscles and to transmit signals to the brain. The list of genes associated with Charcot-Marie-Tooth disease continues to grow as researchers study this disorder.

Charcot-Marie-Tooth disease

Definition

Charcot-Marie-Tooth disease (CMT) is the name of a group of inherited disorders of the nerves in the peripheral nervous system causing weakness and loss of sensation in the limbs.

Description

CMT is named for the three neurologists who first described the condition in the late 1800s. It is also known as hereditary motor and sensory neuropathy. It is sometimes called peroneal muscular atrophy, referring to the muscles in the leg that are often affected. The age of onset of CMT can vary anywhere from young childhood to middle adulthood. Symptoms typically begin by the age of 20. For reasons yet unknown, the severity in symptoms can also vary greatly, even among members of the same family.

Although CMT has been described for many years, it has only been since the early 1990s that the genetic causes of many types of CMT have become known. Knowledge about CMT has accordingly increased dramatically within the two past decades as a result of the significant advances in genetics.

The peripheral nerves

CMT affects the peripheral nerves, those groups of nerve cells carrying information to and from the spinal

cord. It decreases their ability to carry motor commands to muscles, especially those furthest from the spinal cord located in the feet and hands. As a result, the muscles connected to these nerves eventually weaken. CMT also affects the sensory nerves that carry information from the limbs to the brain. Therefore, people with CMT also have sensory loss. This causes symptoms such as difficulties with balance, or not being able to tell if something is hot or cold.

Although multiple types of CMT may be grouped together based on the types of nerve problems of clinical findings, the disease often is classified according to several specific types. The types are distinguished by how CMT affects nerve function and by the genetic cause. Type X CMT is caused by mutations in a gene on the X chromosome, one of the two sex chromosomes. Type 1 CMT is characterized by abnormalities in myelin, the protective substance that covers nerve cells. Type 2 CMT is characterized by abnormalities in the axon fiber that extends from a nerve cell and transmits nerve impulses. Intermediate forms of CMT display abnormalities in both axons and myelin. Type 4 CMT affects either the axon or myelin. Types 1, 2, 4, and intermediate forms are further categorized by subtypes (such as 1A, 2A, 4A), distinguished by the specific gene that is altered. No universal system has yet been adopted to classify types of CMT, and other names are used to describe this disorder. For example, Roussy-Levy syndrome is a form of type 1 CMT, type 1B. Dejerine-Sottas syndrome is a severe early childhood form of CMT that may be type 1 or type 4 depending on the specific gene that is altered.

Genetic profile

CMT is caused by changes (mutations) in any one of a number of genes that carry the instructions to make the peripheral nerves. Genes contain the instructions for how the body grows and develops before and after a person is born. As of 2021, mutations in 88 genes had been identified as responsible for one of the many types of CMT. These include the *AARS*, *BSCL2*, *DNM2*, *EGR2*, *FGD4*, *GARS*, *GDAP1*, *GJB1*, *HSPB1*, *KIAA0274*, *KIF1B*, *LITAF*, *LMNA*, *MFN2*, *MPZ*, *MTMR2*, *NDRG1*, *NEFL*, *PMP22*, *PRX*, *RAB7A*, *SBF2*, *SH3TC2*, and *YARS* genes, along with others.

Increasingly, CMT is categorized by the specific gene that is altered. Type 1 is caused by mutations in the following genes: *PMP22* (subtypes 1A and 1E), *MPZ* (subtype 1B), *LITAF* (subtype 1C), *EGR2* (subtype 1D), and *NEFL* (subtype 1F). Alterations in the following genes cause type 2 CMT disease: *KIF1B* and *MFN2* (subtype 2A), *RAB7A* (subtype 2B), *LMNA* (subtype 2B1), *TRPV4* (subtype 2C), *BSCL2* and *GARS* (subtype 2D), *NEFL* (subtype 2E), *HSPB1* (subtype 2F), *MPZ*

(subtypes 2I and 2J), *HSPB5* (subtype 2L), and *GDAP1* (subtype 2K). Type 4 CMT is caused by mutations in the following genes: *GDAP1* (subtype 4A), *MTMR2* (subtype 4B1), *SBF2* (subtype 4B2), *SH3TC2* (subtype 4C), *NDRG1* (subtype 4D), *EGR2* (subtype 4E), *FGD4* (subtype 4H), *FIG4* (subtype 4J), and *PRX* (subtype 4F). Intermediate CMT is caused by mutations in the *DNM2*, *YARS*, *MPZ*, and *GDAP1* genes. Type X CMT disease is caused by a mutation in the *GJB1* and *PRPS1* genes.

CMT1

The most common type of CMT is called CMT1A. It is often caused by a mutation in a gene called peripheral myelin protein 22 (*PMP22*) located on chromosome 17. The function of this gene is to make a protein (*PMP22*) that makes up part of the myelin. In most people who have CMT, the mutation that causes the condition is a duplication (doubling) of the *PMP22* gene. Instead of having two copies of the *PMP22* gene (one on each chromosome), there are three copies. It is not known how this extra copy of the *PMP22* gene causes the observed symptoms. A small percentage of people with CMT1A do not have a duplication of the *PMP22* gene, but rather have a point mutation in the gene. A point mutation is a misprint in the gene that causes it to work incorrectly.

CMT1B is caused by a mutation in a gene called myelin protein zero (*MPZ*) located on chromosome 1. The function of this gene is to make the layers of myelin stick together as they are wrapped around the axon. The mutations in this gene are point mutations because they involve a change (either deletion, substitution, or insertion) at one specific component of a gene.

Hereditary neuropathy with liability to pressure palsies (HNPP)

HNPP is a condition that is also caused by a mutation in the *PMP22* gene. The mutation is a deletion resulting in only one copy of the *PMP22* gene instead of two. People who have HNPP may have some of the signs of CMT. However, they also have episodes where they develop weakness and problems with sensation after compression of certain pressure points, such as the elbows or knee. These symptoms will often resolve after a few days or weeks, but sometimes they are permanent.

CMT2

CMT2 results from abnormalities in the axon of the peripheral nerve cell rather than the myelin sheath. There are many subtypes of CMT2, designated by the letters from A–L. Each subtype is characterized by the mode of inheritance and associated clinical features. As of 2021, the genetic loci have been identified for some subtypes.

KEY TERMS

Axon—Very thin, wire-like extension of nerve cells.

Myelin—A fatty sheath surrounding nerves in the peripheral nervous system that helps them conduct impulses quickly.

Nerve conduction testing—Procedure that measures the speed at which impulses move through the nerves.

Neuropathy—A condition caused by nerve damage. Major symptoms include weakness, numbness, paralysis, or pain in the affected area.

Peripheral nerves—Nerves throughout the body that that communicate motor and sensory information to and from the spinal cord.

CMTX

Another type of CMT, called CMTX, is usually considered a subtype of CMT1 because it affects the myelin, but it has a different type of inheritance than type 1 or type 2. In CMTX, the CMT-causing gene is located on the X chromosome and is called connexin 32 (*Cx32*). The function of this gene is to code for a class of protein called connexins that form tunnels between the layers of myelin.

CMT3

In the past a condition called Dejerine-Sottas disease was referred to as CMT3. This is a severe type of CMT in which symptoms begin in infancy or early childhood. It is now known that this is not a separate type of CMT. People who have onset in infancy or early childhood often have mutations in the *PMP22* or *MPZ* genes.

CMT4

CMT4 consists of several different subtypes of autosomal recessive demyelinating motor and sensory neuropathies. Each neuropathy subtype is caused by a different genetic mutation, may affect a particular ethnic population, and produces distinct physiologic or clinical characteristics. Patients with CMT4 generally develop symptoms of leg weakness in childhood and by adolescence they may not be able to walk.

Inheritance

Autosomal dominant inheritance

CMT1A and 1B, HNPP, and all of the subtypes of CMT2 have autosomal dominant inheritance. Autosomal refers to the first 22 pairs of chromosomes that are the

same in males and females. Therefore, males and females are affected equally in these types. In a dominant condition, only one gene of a pair needs to have a mutation in order for a person to have symptoms of the condition. Therefore, anyone who has these types has a 50%, or one in two, chance of passing CMT on to each of their children. This chance is the same for each pregnancy and does not change based on the number of previous children.

X-linked inheritance

CMTX has X-linked inheritance. Since males only have one X chromosome, they only have one copy of the *Cx32* gene. Thus, when a male has a mutation in his *Cx32* gene, he will have CMT. However, females have two X chromosomes and therefore have two copies of the *Cx32* gene. If they have a mutation in one copy of their *Cx32* genes, they will only have mild to moderate symptoms of CMT that may go unnoticed. This is because their normal copy of the *Cx32* gene produces sufficient amounts of myelin.

Women pass on one or the other of their X chromosomes to their children—sons or daughters. If a woman with a *Cx32* mutation passes her normal X chromosome, she will have an unaffected son or daughter who will not pass CMT on to their children. If the woman passes the chromosome with *Cx32* mutation on she will have an affected son or daughter, although the daughter will be mildly affected or have no symptoms. Therefore, a woman with a *Cx32* mutation has a 50%, or one in two, chance of passing the mutation to her children; a son will be affected, and a daughter may only have mild symptoms.

When males pass on an X chromosome, they have a daughter. When they pass on a Y chromosome, they have a son. Since the *Cx32* mutation is on the X chromosome, a man with CMTX will always pass the *Cx32* mutation on to his daughters. However, when he has a son, he passes on the Y chromosome; the son will not be affected. Therefore, an affected male passes the *Cx32* gene mutation on to all of his daughters, but to none of his sons.

Autosomal recessive inheritance

CMT4 has autosomal recessive inheritance. Boys and girls are equally affected. In order for a person to have CMT4, they must have a mutation in both of their CMT causing genes—one inherited from each parent. The parents of an affected person are called carriers. They have one normal copy of the gene and one copy with a mutation. Carriers do not have symptoms of CMT. Two carrier parents have a 25%, or one in four, chance of passing CMT on to each of their children.

Demographics

As of 2021, Charcot-Marie-Tooth disease was considered the most common inherited disorder involving the peripheral nerves, affecting an estimated 150,000 people in the United States. It is known to occur in all races and ethnic groups. Worldwide, this disorder affects about 1 in 3,300 people.

Signs and symptoms

The onset of symptoms is highly variable, even among members of the same family. Symptoms usually progress very slowly over a person's lifetime. The main problems caused by CMT are weakness and loss of sensation, especially in the feet and hands. The first symptoms are usually problems with the feet such as high arches and problems with walking and running. Tripping while walking and sprained ankles are common. Muscle loss in the feet and calves leads to "foot drop" where the foot does not lift high enough off the ground when walking. Complaints of cold legs are common, as are cramps in the legs, especially after exercise.

In many people, the fingers and hands eventually become affected. Muscle loss in the hands can make fine movements such as working buttons and zippers difficult. Some patients develop tremor in the upper limbs. Loss of sensation can cause problems such as numbness and the inability to feel if something is hot or cold. Most people with CMT remain able to walk throughout their lives.

Diagnosis

Diagnosis of CMT begins with a careful neurological exam to determine the extent and distribution of weakness. A thorough family medical history should be taken at this time to determine if other people in the family are affected. Testing also may be performed to rule out other causes of neuropathy.

A nerve conduction velocity test should be performed to measure how fast impulses travel through the nerves. This test may show characteristic features of CMT, but it is not diagnostic of CMT. Nerve conduction testing may be combined with electromyography (EMG), an electrical test of the muscles.

A nerve biopsy (removal of a small piece of the nerve) may be performed to look for changes characteristic of CMT. However, this testing is not diagnostic of CMT and is usually not necessary for making a diagnosis.

Definitive diagnosis of CMT is made only by genetic testing, usually performed by drawing a small amount of blood. Testing may not be available to detect all mutations that cause CMT. However, research is progressing rapidly and new testing is often made available every

QUESTIONS TO ASK YOUR DOCTOR

- My spouse and I are planning to have children. What are the chances that one of our children will have Charcot-Marie-Tooth disease?
- Will surgery be helpful in treating our child's Charcot-Marie-Tooth disease?
- What type of specialist should we consult about our child's Charcot-Marie-Tooth disease?

few months. All affected members of a family have the same type of CMT. Therefore, once a mutation is found in one affected member, it is possible to test other members who may have symptoms or are at risk of developing CMT.

Prenatal diagnosis

Testing during pregnancy to determine whether an unborn child is affected is possible if genetic testing in a family has identified a specific CMT-causing mutation. This can be done after 10–12 weeks of pregnancy using a procedure called chorionic villus sampling (CVS). CVS involves removing a tiny piece of the placenta and examining the cells. Testing can also be done by amniocentesis after 16 weeks gestation by removing a small amount of the amniotic fluid surrounding the baby and analyzing the cells in the fluid. Each of these procedures has a small risk of miscarriage associated with it. Those who are interested in learning more should check with their doctor or genetic counselor. Couples interested in these options should obtain genetic counseling to carefully explore all of the benefits and limitations of these procedures.

Treatment and management

There is no cure for CMT. However, physical and occupational therapy are an important part of CMT treatment. Physical therapy is used to preserve range of motion and minimize deformity caused by muscle shortening, or contracture. Braces are sometimes used to improve control of the lower extremities and can help tremendously with balance. After wearing braces, people often find that they have more energy because they are using less energy to focus on their walking. Occupational therapy is used to provide devices and techniques that can assist tasks such as dressing, feeding, writing, and other routine activities of daily life. Voice-activated software can also help people who have problems with fine motor control.

Understanding of the molecular basis of CMT continues to increase at a rapid pace. In addition, the neurophysiologic deficits and clinical problems associated with CMT are more clearly understood. The precise genetic cause of many types of CMT has now been determined. Advances in molecular biology and genetic manipulation techniques have allowed doctors to begin to understand how specific genetic mutations result in disease onset, progression, and symptoms for patients.

It is very important that people with CMT avoid injury that causes them to be immobile for long periods of time. It is often difficult for people with CMT to return to their original strength after injury.

There is a long list of medications that should be avoided, if possible, by people diagnosed with CMT, such as hydralazine (Apresoline), vitamin megadoses (A, B₆, and D), paclitaxel (Taxol), and large intravenous doses of penicillin. Complete lists are available from the CMT support groups. People considering taking any of these medications should weigh the risks and benefits with their physician.

Prognosis

The symptoms of CMT usually progress slowly over many years, but do not usually shorten life expectancy. Most people with CMT do not need to use a wheelchair during their lifetime, but are able to lead full and productive lives despite their physical challenges.

CHARGE syndrome

Definition

CHARGE syndrome is a group of major and minor malformations that have been observed to occur together more frequently than expected by chance. The name of the syndrome is an acronym for some of its features:

- C—Coloboma and/or cranial nerves
- H—Heart defects
- A—Atresia choanae
- R—Retarded growth and development
- G—Genital anomalies
- E—Ear anomalies

While these features have classically been used for identification of affected individuals, many other malformations and medical problems have been observed to occur with this syndrome.

Description

CHARGE syndrome was first described in 1979 as an association of multiple congenital anomalies, all of which included choanal atresia, meaning the blocking of the choanae, the passages from the back of the nose to the throat that allow breathing through the nose. Soon after, several other papers were published describing similar patients who all had both choanal atresia and coloboma—that is, a cleft or failure to close off the eyeball. In 1981, the CHARGE acronym was proposed to describe the features of the condition. Due to the large number of patients described since 1979, CHARGE is now regarded as a recognizable syndrome. Additionally, in 2004, loss-of-function mutations in the *CDH7* gene were shown to cause CHARGE syndrome. The majority of patients with a clinical diagnosis of CHARGE syndrome are found to have a mutation in the *CDH7* gene. However, for the remaining 10%, the cause for the condition remains unclear. Crucial development of the choanae, heart, ear, and other organs occurs 35–45 days after

conception and any disruption in development during this time is believed to lead to many of the features of the syndrome.

Infants with CHARGE syndrome generally have difficulty with feeding and most of those affected have intellectual disability. About half die during the first year of life from respiratory insufficiency, central nervous system (CNS) malformations, and bilateral choanal atresia.

Genetic profile

Up to 90% of individuals with a clinical diagnosis of CHARGE syndrome have a mutation in the *CDH7* gene. Additionally, many individuals suspected of having CHARGE syndrome, but not meeting clinical diagnostic criteria, are also found to carry a *CDH7* mutation. When both individuals with a clinical diagnosis of CHARGE syndrome and those that are highly suspicious for the syndrome are analyzed, mutations in *CHD7* account for about 70% of cases.

CHARGE syndrome, when caused by *CDH7* mutations, is inherited in an autosomal dominant fashion. Most cases of CHARGE syndrome are the first in the family and caused by *de novo* mutations. There are few familial cases known and it is believed most are due to germline mosaicism. If a parent has CHARGE syndrome, the risk for children also having CHARGE syndrome is 50%. However, if neither parent has CHARGE syndrome, the chance of the parents having a second child with CHARGE syndrome is around 1%–2%.

In addition, some patients with CHARGE syndrome also have features of another condition called DiGeorge sequence, which involves an immune deficiency, characteristic heart abnormalities, and distinct craniofacial features. Many patients with DiGeorge sequence have a missing chromosome 22q11. Therefore, newly diagnosed cases of CHARGE syndrome without a confirmatory *CHD7* mutation should have molecular studies to rule out 22q11.2 deletions and other cytogenetic abnormalities.

Demographics

The incidence of CHARGE syndrome is approximately 1 in 10,000. However, this is probably an underestimate of the true number of people affected. The incidence is likely to increase as the diagnostic features of the condition are refined and milder cases are diagnosed. CHARGE syndrome affects males more seriously than females, resulting in a higher number of females who survive. The cause of this difference is unclear. The syndrome has not been reported more often in any particular race or geographic area.

KEY TERMS

Cryptorchidism—A condition in which one or both testes fail to descend normally.

Germline mosaicism—A rare event that occurs when one parent carries an altered gene mutation that affects his or her germline cells (either the egg or sperm cells) but is not found in the somatic (body) cells.

Phenotype—The physical expression of an individual's genes.

Variable expressivity—Differences in the symptoms of a disorder between family members with the same genetic disease.

Signs and symptoms

The majority of individuals with CHARGE syndrome have a mutation in the *CHD7* gene. For individuals with a clinical diagnosis but without an identifiable *CHD7* mutation, the disorder is believed to be caused by a disruption of fetal growth during the first three months of pregnancy. A disruption during this period of pregnancy affects many different organ systems undergoing development. There are no teratogens known to increase the risk for CHARGE syndrome.

Choanal atresia

Choanal atresia, the narrowing of passages from the back of the nose to the throat, may occur on one or both sides (bilateral) of the nose. This condition usually leads to breathing difficulties shortly after birth. Bilateral choanal atresia may result in early death, and surgery is often required to open up the nasal passages. Choanal atresia is also often accompanied by hearing loss. Since bilateral choanal atresia is rare, CHARGE syndrome should be considered in all babies with this finding. Fifty to sixty percent of children diagnosed with CHARGE syndrome have choanal atresia.

Heart abnormalities

Seventy-five to eighty-five percent of children with CHARGE syndrome have heart abnormalities. Many are minor defects, but many require treatment or surgery. Some of the heart problems seen in CHARGE syndrome are very serious (e.g., tetralogy of Fallot) and life-threatening. Every child with a diagnosis of CHARGE syndrome should have an echocardiogram, a test that uses sound waves to produce pictures of the heart.

QUESTIONS TO ASK YOUR DOCTOR

- Where does the name “CHARGE syndrome” come from?
- What are the symptoms associated with CHARGE syndrome?
- What do we know about the way in which CHARGE syndrome is transmitted from generation to generation?
- What is the long-term prognosis for a child diagnosed with CHARGE syndrome?

Coloboma and eye abnormalities

A coloboma is a cleft or failure to close off the eyeball properly. This can result in a keyhole-shaped pupil or abnormalities in the retina of the eye or its optic nerve. The condition is visible during an ophthalmology exam. Colobomas may or may not cause visual changes. About 80% of children with CHARGE syndrome have colobomas, and the effect on vision varies from mild to severe. Other eye abnormalities include microphthalmia (small eye slits) or anophthalmia (no eyes). Consistent eye examinations are recommended for children diagnosed with the syndrome.

Ear abnormalities and deafness

At least 90% of patients with CHARGE syndrome have either external ear anomalies or hearing loss. The most common external ear anomalies include low-set ears, asymmetric ears, small ear lobes, or absent ear lobes. The degree of hearing loss varies from mild to severe. It is important for all patients to have regular hearing exams over time so that changes in sound perception can be detected. Hearing aids are used as soon as hearing loss is detected. Some patients require corrective surgery of the outer ear, so that a hearing aid can be worn. Children with CHARGE syndrome often develop ear infections and this can affect hearing over time as well.

Cranial nerve defects

Defects related to the formation of the cranial nerves during fetal development are common in patients with CHARGE syndrome. The defects include anosmia (inability to smell), facial palsy, hearing loss, and swallowing difficulty. Facial palsy is the inability to sense or control movement of part of the face. This usually occurs on one side of the face, which, in affected individuals, results in a characteristic asymmetric and expressionless look. Swallowing problems

can also occur along with several different defects in the formation of the throat.

Facial features

The facial features of CHARGE syndrome are considered minor diagnostic signs because they are not as obvious as the facial features of other genetic syndromes. However, many patients have facial asymmetry, a small and underdeveloped jaw, a broad forehead, a square face, arched eyebrows, and external ear malformations.

Growth and developmental delays

Most babies with CHARGE syndrome have normal length and weight at birth. Difficulty with feeding and the presence of other malformations often leads to weight loss, so that these babies usually weigh less for their age. Teenagers are also often shorter than average due to a delay in the onset of puberty. In a small number of patients, growth delay is due to a lack of growth hormone.

There are serious delays in motor development of children with CHARGE syndrome as well. Many children have low muscle tone and difficulty with balance that leads to delays in walking. Physical therapy is often helpful. Most children with CHARGE syndrome are identified as having an intellectual disability. However, successful treatment of other features of the condition can improve learning potential. Therefore, assessments made before other medical problems are addressed are often more pessimistic than later exams.

Urogenital abnormalities

Underdevelopment of the genitals occurs in at least half of the male patients diagnosed with CHARGE syndrome and in some females as well. Abnormalities of genitalia in males include an underdeveloped penis (micropenis or microphallus) and testicles that fail to descend to the scrotum (cryptorchidism). In females, there may be overgrowth or underdevelopment of the labia or clitoris. Information concerning the fertility of patients is not available. About 25% of children have renal abnormalities that may lead to repeated infections. A renal ultrasound is indicated in children with the syndrome.

Central nervous system anomalies

In one series of tested patients, CNS anomalies were noted in 83% of the patients who underwent brain imaging tests. These tests are used to produce pictures of the brain such as MRI, CT scan, and ultrasound, or after autopsy. The CNS anomalies included diminution of the size of the brain (cerebral atrophy), asymmetry, and midline defects such as partial development (e.g., agenesis of the corpus callosum). In addition, brain stem dysfunction has also

been observed after birth, a disorder that can cause respiratory and swallowing problems. These findings were associated with a poor prognosis.

Associated anomalies

Many other features have been reported in patients with CHARGE syndrome. Some of these include a cleft lip and/or palate, dental anomalies, absence of the thymus and parathyroid glands that lead to immunodeficiency (the inability of the body to produce a normal immune response), seizures, abnormally low levels of calcium (hypocalcaemia) or sugar (hypoglycemia) in the body, obstruction of the anal opening (imperforate anus), groin hernias, curvature of the spine (scoliosis), skeletal anomalies, body temperature regulation problems, and umbilical hernias.

Diagnosis

The clinical presentation of CHARGE syndrome is extremely variable. A diagnosis is made clinically by fulfilling a combination of major and minor diagnostic criteria. A mutation in the *CHD7* gene is useful in guiding the diagnostic process, as not all patients with *CHD7* mutations meet all criteria required for a clinical diagnosis. Clinical diagnostic criteria for CHARGE syndrome were initially established in 1981 and have undergone several revisions. Major diagnostic characteristics of CHARGE syndrome include choanal atresia or stenosis, ocular coloboma, cranial nerve abnormalities, and the characteristic CHARGE syndrome ear. Minor characteristics include genital hypoplasia, developmental delay, cardiovascular malformation, growth deficiency, orofacial cleft, tracheoesophageal fistula, and distinctive facial features. A clinical diagnosis of CHARGE syndrome is made when an individual has all four major criteria, or three major and one minor criterion. A possible diagnosis of CHARGE syndrome is made when an individual has two major criteria and several minor criteria.

Prenatal diagnosis and preimplantation genetic diagnosis (PGD) can be performed when the familial *CHD7* mutation is known. The condition may also be suspected when a prenatal ultrasound reveals fetal growth restriction, CNS malformations, heart defects, and urinary tract malformations. In one series, 37.5% of patients diagnosed with CHARGE were noted to have an abnormal feature detected on ultrasound.

There are several other conditions that include signs similar to CHARGE syndrome. These include VACTERL association (for vertebral, anal, cardiac, tracheoesophageal, renal, and limb abnormalities), velocardiofacial (VCF) syndrome (deletion 22q11 syndrome), and prenatal retinoic acid exposure (Accutane embryopathy).

Treatment and management

Treatment for CHARGE syndrome is specific to the features present in each child. Choanal atresia can be treated with dilatations of the choanae or nasal passages. Heart defects may require surgery. Children with CHARGE syndrome should get ophthalmology and hearing screens every six months. Plastic surgery is sometimes needed for corrections of ear malformations or facial asymmetry. Medications are needed when seizures are present. Growth hormone is sometimes prescribed for growth delay or underdeveloped genitalia.

A developmental evaluation and a plan for special-needs education are required. Patients with CHARGE syndrome who have both hearing and vision difficulty should receive care from childhood educators experienced in dual sensory impairment. Once these children establish a system of mobility and communication, the degree of developmental delay may improve. Lengthy hospital stays for children with CHARGE syndrome may limit the ability of specialists to work with the child in the early months. When the major hospitalizations are completed, development may improve as the result of regular care by the appropriate child specialists. Other learning problems have been noted and should also be addressed if present. These include attention deficit disorder, autism, and obsessive-compulsive disorder. Parents are often in the position of coordinating the many components of special-needs education for their children. The national and international support groups for CHARGE syndrome are able to provide information and assistance in this area.

Prognosis

It has been noted in several studies that about half of patients diagnosed with CHARGE syndrome die from complications of the condition. One study suggests that 40% of those die shortly after birth. Factors that appear to undermine survival include the presence of CNS malformations, bilateral choanal atresia, TE fistula, and male sex. Heart abnormalities and brain stem dysfunctions were not found to be related to poor prognosis. Significant hospitalizations are needed for most children with CHARGE syndrome.

Chediak-Higashi syndrome

Definition

Chediak-Higashi syndrome (CHS) is a very rare, often fatal, genetic disorder that disrupts the function of lysosomes—the recycling organelles within cells—and similar subcellular structures. In particular, CHS affects the function of immune-system cells called phagocytes, blood-clotting cells called platelets, and pigment-producing cells called melanocytes, resulting in a wide range of serious symptoms. CHS also affects nerve cells, resulting in neurologic symptoms. CHS is caused by mutations (changes) in the *LYST* gene that produces the lysosomal trafficking regulator protein. Because of its severe immune-system effects, CHS is considered a primary immunodeficiency disorder.

Description

CHS was first described by Beguez Cesar in 1943, but was named for the scientists Chédiak and Higashi, who elaborated on the disorder in 1952 and 1954 respectively. The disease progresses from a stable phase to an accelerated phase in which infections, a lymphoma-type illness, and/or organ failure are frequently fatal.

CHS particularly affects immune-system cells, especially phagocytes, melanin production, and platelets. Beginning in infancy or early childhood, immunodeficiency from CHS results in susceptibility to repeated and persistent serious or life-threatening viral and bacterial infections. Children with CHS who are not successfully treated usually enter the accelerated phase of the disease, in which immune-system white blood cells divide and proliferate out of control, invading organs throughout the body, and causing a potentially fatal illness similar to lymphoma. CHS also results in abnormal melanosomes. These are subcellular structures in cells called melanocytes that are similar to lysosomes and that produce melanin—the pigment that gives skin, hair, and eyes their color. This often results in a condition called oculocutaneous albinism. Affected individuals usually have light-colored skin and hair, sensitivity to sunlight, and various vision problems that result from a lack of pigment in the iris and retina of the eye. Defective platelets lead to blood-clotting problems, easy bruising, and abnormal bleeding.

Rarely, a milder form of CHS develops in adulthood. Although this form of CHS is less likely to cause severe infections or pigmentation changes, affected individuals are at risk for progressive neurological problems. These include tremor, movement difficulties, imbalance, weakness, loss of sensation in the arms and legs, and cognitive decline.

Genetic profile

CHS is an autosomal recessive disorder. "Autosomal" means that the defective *LYST* gene responsible for CHS is located on a chromosome other than the X or Y sex chromosomes, and is therefore equally likely to affect males and females. "Recessive" means that to be affected by CHS, an individual must inherit two defective copies of the gene, one from each parent. Those parents are carriers who have one mutated copy of the gene, one normal copy, and do not have symptoms of the disorder. However, when both parents carry a defective *LYST* gene, each of their offspring has a 25% risk of inheriting two mutated copies and developing CHS. Each child of a carrier has a 50% risk of inheriting the mutant gene from the parent.

The *LYST* gene, also known as *CHS1* or lysosomal trafficking regulator, is located on the long arm (q) of chromosome 1 (positions 1q42.1–q42.2). *LYST* encodes a protein that helps transport toxic substances, digested pathogens such as bacteria, and worn-out cell components to lysosomes inside cells, where digestive enzymes break them down and recycle the molecules. At least 30 different mutations (changes) in the *LYST* gene can cause CHS by affecting the size, structure, and function of lysosomes and related subcellular compartments. Most of the

KEY TERMS

Autosomal recessive—A pattern of inheritance in which two copies of an abnormal gene must be present in order for the disease or trait to develop.

Carrier—Having one abnormal gene for a trait, such as Chediak-Higashi syndrome, and one normal gene for the trait (a heterozygote), without signs or symptoms of the disorder but with the possibility of passing the abnormal gene on to offspring.

Lymphoma—Cancer of the lymphatic tissue.

Lysosomes—Membrane-enclosed compartments within cells, in which digestive enzymes break down and recycle toxins, infectious organisms, and worn-out cellular components.

LYST—The gene that encodes the lysosomal trafficking regulator protein that is required for normal functioning of lysosomes and similar subcellular compartments.

Melanin—A pigment produced by the body that gives color to the skin, hair, and eyes.

Melanocytes—Cells that produce melanin.

Melanosomes—Subcellular structures, similar to lysosomes, that produce melanin in melanocytes.

Oculocutaneous albinism—An absence of pigment in the skin, hair, and eyes resulting in sun sensitivity and vision problems.

Phagocytes—Immune-system white blood cells that engulf and digest bacteria and other foreign material and debris.

Platelets—Small cell-like bodies in the blood that are involved in clot formation.

mutations that result in severe CHS in childhood produce a short, nonfunctional lysosomal trafficking regulator protein. Mutations that result in the milder adult form of the disorder usually change just one amino acid in the protein, so that the *LYST* protein retains some function.

LYST mutations result in lysosomes that are abnormally large and interfere with cellular functions. For example, immune-system cells with enlarged lysosomes are unable to respond appropriately to disease-causing bacteria. Melanosomes are also abnormally large in CHS, and the melanin becomes trapped in them, making them unable to provide pigment to the skin, hair, and eyes. Abnormal lysosome-like structures in platelets are

believed to be responsible for abnormal blood clotting. Abnormal lysosomes in nerve cells are thought to be responsible for the neurologic symptoms of CHS.

Demographics

CHS is extremely rare—only about 500 cases have been described worldwide. It often affects families that have a history of intermarriage among close relatives, which increases the risk that a child will inherit two defective *LYST* genes. In addition to humans, CHS also occurs in cattle, cats, mice, rats, and foxes.

Signs and symptoms

Symptoms of CHS include:

- silver hair, light-colored eyes, light sensitivity, vision problems, and jerky eye movements caused by melanin deficiency (albinism)
- frequent, often severe and persistent infections of the lungs, skin, and mucous membranes
- fevers
- gum disease
- easy bruising and nosebleeds
- nerve problems, such as numbness, tremor, or seizures
- weakness
- poor coordination

In the accelerated phase, CHS-affected children may have an enlarged liver and spleen (hepatosplenomegaly), low blood platelet counts (thrombocytopenia), low counts of immune-system white blood cells called neutrophils (neutropenia), and low red blood cell counts (anemia). Abnormal cells may infiltrate and suppress the bone marrow, further lowering blood cells counts and causing abnormal bleeding, life-threatening infections, organ failure, and lymphoma-like illness.

Diagnosis

Diagnosis of CHS is based on microscopic examination of blood cells, and possibly bone marrow cells, that reveal giant lysosomal granules within certain white blood cells. Genetic testing can reveal mutations in the *LYST* gene, and can also determine if one or both parents are carriers of *LYST* mutations. Prenatal genetic testing for CHS is available if *LYST* mutations have been identified in family members.

A physical exam may reveal a swollen spleen or liver, or yellowing of the skin or eyes (jaundice) from liver dysfunction. Blood counts, nervous system tests, and imaging of internal organs will be performed.

QUESTIONS TO ASK YOUR DOCTOR

- How did my child inherit Chediak-Higashi syndrome?
- Can my partner and I have genetic counseling and/or testing for the gene that causes Chediak-Higashi syndrome?
- What is the risk that we will have another child with Chediak-Higashi syndrome?
- Will my child with Chediak-Higashi syndrome be able to have a bone marrow transplant?
- What is the prognosis for a child who has been diagnosed with Chediak-Higashi syndrome?

Treatment and management

Other than antibiotics and antiviral medications for preventing and treating infections, the only treatment for CHS is a bone marrow transplant, which can cure the immunodeficiency. The earlier the bone marrow transplant is performed, the better the outcome. Once the disease enters the accelerated phase, however, it is very difficult to treat. Surgery may be required to drain abscesses. The lymphoma-like illness may be treated with steroids and anticancer drugs, but is usually fatal within months.

Prognosis

In the past, most children with CHS died within the first decade of life, although there have been reports of people surviving into their 30s. About 80% of children with CHS eventually enter the accelerated phase. Death usually results from chronic infections or lymphoma-like illness in the accelerated phase. However, bone marrow transplants have now enabled a majority of children with CHS to survive and thrive for at least 13 years following treatment.

Chondrodysplasia punctata

Definition

Chondrodysplasia punctata is a group of inherited disorders affecting the skeletal system, skin, eyes, and mental functioning.

Description

Chondrodysplasia punctata is characterized by shortened bones; punctated or dot-like calcification deposits in the cartilage; and abnormal peroxisomes. Peroxisomes

are structures within cells that help remove toxins from the body.

There are three main variations of chondrodysplasia punctata: rhizomelic chondrodysplasia punctata, non-rhizomelic chondrodysplasia punctata, and Sheffield type. Within these variations, there are different syndromes characterized by distinct anomalies and modes of transmission.

Rhizomelic chondrodysplasia punctata is characterized by shortened long bones in the arms and legs, abnormalities of the spine, stippled or dotted appearance to the cartilage, scaling of the skin, cataracts, and profound intellectual disability. This type of chondrodysplasia punctata is caused by a single-gene mutation. Most fetuses with rhizomelic chondrodysplasia punctata die *in utero* or shortly after birth. Those that survive usually die within the first ten years of life.

Non-rhizomelic chondrodysplasia punctata, sometimes called Conradi-Hünemann disease, encompasses several distinct syndromes with unique characteristics and modes of transmission. Happle's chondrodysplasia is one type of non-rhizomelic chondrodysplasia characterized by asymmetry of the arms and legs, distinctive skin sores or scales, and cataract often affecting only one eye. Intelligence is usually normal. This type predominantly affects women and is usually lethal in males, generally resulting in miscarriage of male fetuses.

Another type of non-rhizomelic chondrodysplasia is brachytelephalangic chondrodysplasia punctata, which is characterized by severe facial abnormalities, abnormalities of the cartilage in the trachea and larynx, calcifications in the feet and legs, and hypoplastic, or small little fingers and little toes. The abnormal facial features of this syndrome are called Binder's maxillonasal dysostosis and include abnormalities of the upper jaw, flat nose, cleft palate, smooth or absent philtrum, and small teeth. These facial malformations and anomalies of the trachea and larynx can cause serious breathing difficulties for newborns. Infants with brachytelephalangic chondrodysplasia punctata often require respiratory therapy. This syndrome primarily affects boys and may cause intellectual disability.

The Sheffield type of chondrodysplasia punctata is a mild form of the disorder affecting males and females equally. It is characterized by the abnormal dotted cartilage formations, flattened facial features, and intellectual disability. This is considered a milder form of the disorder. The inheritance has not been determined, and the genetic mutation responsible has not been identified.

Genetic profile

The genetic cause of rhizomelic chondrodysplasia punctata is well documented. Many of the anomalies result from abnormalities of the perisomes and the

resulting inability of the body to process and remove toxic enzymes and proteins. Perisomes are structures found within cells that remove toxins from cells and therefore from the body. Researchers have identified a genetic mutation of the peroxisome biogenesis factor 7 (*PEX7*) as causing these perisomal abnormalities. This mutation is transmitted as an autosomal recessive trait. Autosomal recessive conditions are carried on a chromosome that is not involved in determining sex and must be present in both parents to be transmitted to a child. In the case of rhizomelic chondrodysplasia, the *PEX7* gene is found on chromosome 4 in the 4p16 locus.

Non-rhizomelic chondrodysplasia is an X-linked disorder, which means the mutations responsible for causing it are located on the X chromosome. There are two types of X-linked transmission: dominant and recessive. In X-linked dominant traits, the condition will manifest if only one copy of the genetic mutation is present. Many X-linked dominant conditions are milder in females than in males, because genetic material on the second X chromosome can reduce the effects of the mutation. X-linked dominant mutations can have severe effects in females and may be lethal in males. Happle's chondrodysplasia is an X-linked dominant condition resulting from mutations in the emopamil binding protein (*EBP*) gene.

In X-linked recessive traits, the genetic mutation is recessive, meaning the characteristics of the mutation will be seen only when another normal copy of the gene is not present. For this reason, X-linked recessive mutations most frequently affect males. Females must have two mutated copies of the same gene to demonstrate the abnormalities the mutation causes. It is rare for females to be affected by X-linked recessive genetic mutations, but they may be carriers, passing the gene on to their offspring. Brachytelephalangic chondrodysplasia punctata is an X-linked recessive condition caused by a mutation of the arylsulfatase E (*ARSE*) gene and a deletion of the short arm of the X chromosome.

Demographics

Chondrodysplasia punctata is a very rare condition. It affects fewer than 1 in every 100,000 individuals.

The rhizomelic type of chondrodysplasia punctata is an autosomal recessive condition affecting males and females equally. In the non-rhizomelic types of the disorder, Happle's chondrodysplasia punctata affects females almost exclusively and is generally lethal to males. Brachytelephalangic chondrodysplasia punctata is seen more frequently in males; however, it may be seen in females. The milder form of the disorder, Sheffield type, affects females and males equally.

KEY TERMS

Asymmetry—Lack of similar size, length, and shape on both sides of the body.

Autosomal—Describes a genetic trait found on a chromosome that is not involved in determining sex.

Calcification—The process by which tissue becomes hardened by the deposition of calcium.

Cataract—Clouding of the lens in the eye.

Cleft palate—An abnormal opening or cleft between roof of the mouth and the nasal cavity.

Dermatologic—Pertaining to the field of dermatology, the science of the skin and diseases that affect the skin.

Dominant—Describes a genetic trait that is expressed when only one copy of the gene is present.

Hypoplastic—Small.

Ichthyosis—A skin condition characterized by a fish-scale appearance.

In vitro fertilization (IVF)—Sometimes referred to as producing a “test tube baby,” IVF is the fertilization of a human egg outside the body.

Larynx—The voice box.

Microcephaly—A birth defect in which the brain and head are too small.

Mutation—A permanent change in genetic material that is transmittable.

Orthopedic—Pertaining to the field of orthopedics, the science of the bones and diseases of the bones.

Peroxisomes—Structures within the cell that remove toxins from the cell.

Philtrum—The grooved space between the nose and the upper lip.

Prenatal ultrasound—An imaging test using high-frequency sound waves to create images of internal organs. “Prenatal” indicates the test is performed on a fetus while still in the womb.

Prevalence—The number of individuals in a population that have a specific condition.

Punctated—Having a dotted pattern.

Recessive—A genetic trait that is only expressed when another identical recessive gene is present.

Trachea—The windpipe.

Vertebrae—Bony structures of the spine.

X-linked—A genetic trait that is carried on the X chromosome.

X-ray—An imaging test that uses beams of energy to create images of structures within the body.

Signs and symptoms

The symptoms of chondrodysplasia punctata may involve the skeletal system, cartilage, face, eyes, and intellectual functioning. The specific signs and symptoms of this disorder depend on which type is present.

The symptoms of rhizomelic chondrodysplasia punctata can include:

- abnormal hair loss
- cataracts
- cartilage abnormalities
- curvature of the spine
- facial abnormalities
- ichthyosis (scaly skin)
- intellectual disability
- microcephaly
- short stature or dwarfism

The symptoms of non-rhizomelic chondrodysplasia punctata can include:

- abnormalities of the eye

- abnormalities of the cartilage in the larynx and trachea
- asymmetry of the body
- cartilage abnormalities
- dwarfism
- hearing impairment
- heart defects
- intellectual disability
- mid-face abnormalities
- kidney malformations
- prematurity
- punctate vertebrae (dotted appearance in x-rays)
- short and in-curving fingers
- shortened limbs

Diagnosis

For parents who know that they are carriers of the X-linked type of chondrodysplasia punctata, there is a prenatal procedure and test called preimplantation genetic diagnosis (PGD). After in vitro fertilization (IVF), PGD

can test for genetic abnormalities as well as sex before an embryo is implanted.

Prenatal ultrasound may be helpful in diagnosing chondrodysplasia punctata in the fetus. A second trimester ultrasound may detect the characteristic punctated calcifications of the spine and feet. Combined with evidence of shortened limbs, a diagnosis may be made. However, in milder cases of the disorder, the defects may be too subtle for detection by a routine prenatal ultrasound.

A physical examination may diagnose the external features of this disorder, including the facial abnormalities, shortened limbs, curvature of the spine, and ichthyosis.

A definitive diagnosis may be made by x-ray of the limbs and spine. In children one year or younger, punctated calcifications may be seen in the long bones and the feet in the areas of cartilage at the ends of growing bones. This cartilage disappears after the first year of age and is replaced with growth plates. These plates appear normal on x-ray. In adults and older children, the diagnosis is based on shortened bones in the arms and legs, and the presence of other physical characteristics of the disorder.

Treatment and management

The treatment and management of chondrodysplasia punctata is primarily orthopedic and dermatologic. The characteristic stippling or dotted cartilage will disappear as the child ages; however, shortened arms and legs and curvature of the spine require orthopedic treatment. In some cases, surgery may be necessary to help patients whose legs are different lengths.

In some individuals, bone growth may be induced by a surgical bone-lengthening procedure. This procedure involves several surgeries and an extensive recovery period. The bone to be lengthened is cut. Leaving a narrow gap between the two pieces of bone, metal pins are inserted into the bone, and the skin is closed. An external frame is attached to the pins. Gradually, the bone is pulled apart just enough to provide a small gap for the bone to grow into. As the bone grows, the space is widened, and more bone grows. After the bone has healed, the pins are surgically removed.

Spinal abnormalities, such as spinal cord compression and scoliosis, may be treated surgically. A spinal column fusion can relieve the stress on the spinal cord caused by malformations of the spinal column. In a spinal fusion, two or more vertebrae are fused together using bone grafts or metal rods.

Ichthyosis is often most severe at birth and can resolve completely as the child ages. However, in some individuals, the skin lesions may be extensive and long

lasting, leading to recurrent skin infections. Management of ichthyosis involves topical treatment and, in severe cases, bandaging to help prevent infection.

Prognosis

Prognosis of chondrodysplasia punctata depends on the type. The rhizomelic form of this disorder has a very poor prognosis. Most individuals with this type of chondrodysplasia punctata do not survive the fetal period or die shortly after birth. Of those that do survive, life expectancy is ten years or less. Along with the skeletal anomalies, profound intellectual disability is common as well.

The non-rhizomelic type, also known as Conradi-Hünemann disease, can have a better prognosis. Though the condition is extremely rare, a range of outcomes has been reported from death to mildly affected adults. The X-linked dominant type, or Happel's type, is usually lethal to males, and they generally do not survive past the second trimester of pregnancy. However, females with this type usually survive and may have normal intelligence.

The X-linked recessive type called brachytelephalangic chondrodysplasia punctata can have a range of possible prognoses. Because a component of this type is a flat mid-face, small nose, and cartilage abnormalities of the larynx and trachea, these children may have breathing difficulties and may die shortly after birth. If these anomalies are not present or are mild, the prognosis is much better. Individuals with this type of the disorder usually have normal intelligence.

Chondrosarcoma

Definition

Chondrosarcoma is a malignant tumor that produces a special type of connective tissue called cartilage. Malignant tumors have cells that have the ability to invade and are characterized by uncontrolled growth.

Description

Cartilage is a type of connective tissue that acts as a resistant surface. Cells called chondrocytes produce cartilage. Chondrosarcoma is a malignant growth arising in chondrocytes. There are two types of chondrosarcomas, either primary or secondary. Primary chondrosarcomas arise in areas of previously normal bone that are derived from cartilage. Secondary chondrosarcomas are lesions produced from pre-existing cartilage lesions. The chondrosarcoma tumors either produce enlargement or erosion of the area involved. The lesion is classified further as to where the lesion occurs and the grade of the lesion. It is graded from 1 (low-grade) to 3 (high-grade). This classification states that the higher the grade of the tumor, the higher the increased atypia, or abnormal cell growth.

Two noncancerous diseases, Maffucci syndrome and Ollier disease, are similar to chondrosarcoma. Ollier disease, also known as enchondromatosis or dyschondroplasia, is a disorder affecting the growth plates of bone where new bone is deposited. The cartilage laid down is not reabsorbed, and masses form near the ends of the long

KEY TERMS

Atypia—A term for a structural abnormality in a cell.

Cartilage—Supportive connective tissue that cushions bone at the joints or connects muscle to bone.

Computed tomography (CT) scan—An imaging procedure that produces a three-dimensional picture of organs or structures inside the body, such as the brain.

Curettage—A surgical scraping or cleaning.

Enchondromas—Benign cartilaginous tumors arising in the cavity of bone. They have the possibility of causing lytic destruction within the bone.

Excision—Surgical removal.

Lysis—Area of destruction.

Maffucci syndrome—A manifestation of Ollier disease (multiple enchondromatosis) with hemangiomas, which present as soft tissue masses.

Myxoid—Resembling mucus.

Ollier disease—Also termed multiple enchondromatosis. Excessive cartilage growth within the bone extremities that results in benign cartilaginous tumors arising in the bone cavity.

Radiolucent—Transparent to x-ray or radiation. The black area on x-ray film.

Urinary urgency—An exaggerated or increased sense of needing to urinate.

bones such as the thigh bone (femur) and upper arm bone (humerus). Maffucci syndrome has the same abnormalities as Ollier disease as well as soft tissue destruction including the skin. Patients with Maffucci or Ollier disease should have bone scans every three to five years to monitor potential malignant transformations.

Genetic profile

Anomalies of chromosomes 5, 7, 8, and 18 and structural alterations of chromosomes 1, 12, and 15 are commonly found in patients diagnosed with chondrosarcoma. Interestingly, the gene for the area of normal cartilage production, type II collagen, has been found in the same regions as chondrosarcoma. Studies of the tumor suppressor gene, *EXT1*, have shown that changes (mutations) of this gene may also be important in the growth of chondrosarcoma.

Demographics

As of 2021, an estimated 3,610 new cases of bone and joint cancer will be diagnosed per year in the United States.

Primary cancer of bones accounts for less than 0.2% of all cancers. Chondrosarcoma is the second most common primary malignant bone tumor, meaning it did not originate at another site in the body. Osteosarcoma is the most common.

There are conflicting reports as to how much more frequently men are diagnosed with chondrosarcoma than females. Findings range from twice as many males to only slightly more males than females. Chondrosarcoma occurs in people from the age of 30–70 years old, but it most commonly affects people over the age of 40. No ethnic group is affected more frequently than another.

Signs and symptoms

The signs and symptoms vary due to the type of tumor, but pain is typically the first symptom. If it is a fast-growing, high-grade form of chondrosarcoma, then the individual may have very severe pain. A low-grade slow-growing tumor usually produces pain and swelling in the area of the tumor. If the tumor is located in the pelvis or hip area, the individual may have difficulty with urination or urinary urgency. The patient may also have the sensation of a groin pull if the tumor is in the pelvic area.

Diagnosis

Usually, chondrosarcoma is diagnosed with x-ray radiography. X-rays can show soft tissue calcification, where the muscles appear to be forming bone. The appearance of a soft tissue mass that has not yet calcified may also be visible. If the chondrosarcoma is secondary to another type of tumor, the chondrosarcoma may start to erode the edges of the other tumor. This is common when an enchondroma, a type of tumor within the bone shaft, is present. In this case, the chondrosarcoma produces areas of lysis, or destruction of the surrounding tissue.

Biopsy is used to determine the grade of the tumor. Grade 1 chondrosarcomas, or low-grade, slow-growing lesions, have a mild increase of new cell growth. Grade 3 chondrosarcomas are the opposite; they are high-grade and fast-growing, and have a dramatic increase in cellular growth. The more radiolucent or transparent to x-rays the tumor appears, the greater the chance it is a higher grade.

Other imaging tests may also be used. Computed tomography scanning, CT, is an advanced form of x-ray that can also produce bone pictures and help determine how much calcification the tumor is producing. Magnetic resonance imaging, MRI, will aid diagnosis since it can differentiate soft tissues such as muscle and fat. MRI will help determine the amount of malignant degeneration of the chondrosarcoma.

QUESTIONS TO ASK YOUR DOCTOR

- To what stage has my chondrosarcoma progressed?
- What treatments do you recommend for the disease at this point in my life?
- Given my current health status, what prognosis can you make for my recovery from this disorder?
- Are there clinical trials currently underway for treatment of this disease?

Treatment and management

The main course of therapy for chondrosarcoma is surgical removal of the tumor. The amount of surgery depends on the location and the stage of the tumor. Very low-grade tumors may be surgically removed. High-grade chondrosarcomas necessitate more radical operations in which normal tissue is also removed due to the possibility of spread. If the tumor is located in an extremity such as an arm or leg, then amputation, or surgical removal of the extremity, may be necessary in order to prevent metastasis, or spread of the cancer. Chemotherapy and radiotherapy may also be used depending on the type of tumor and the area of the body affected, but are usually not effective.

Prognosis

The higher the grade of a chondrosarcoma, the more likely the tumor will spread and thus worsen the prognosis. One study found the five-year survival rate of patients with grades 1, 2, and 3 to be 90%, 83%, and 43% respectively. This means that five years after the diagnosis of the tumor, 90 out of 100 people with grade 1 were still alive. On the opposite spectrum, 43 out of 100 patients with grade 3 chondrosarcoma survived five years. Therefore the survival rate is very much dependent on the stage of the tumor and also on its location. Size of the tumor is also an important factor. Tumors greater than 4 in. (10 cm) are more likely to become aggressive and spread. When they do spread, or metastasize, they often migrate to the lungs and skeleton.

CHOPS syndrome

Definition

First identified in 2015, CHOPS syndrome is a very rare genetic disorder caused by a mutation in the *AFF4* gene. It is characterized by intellectual impairment, facial abnormalities, heart defects, obesity, pulmonary disorders, and skeletal dysplasia (abnormal development).

Description

On March 2, 2015, geneticists at Children's Hospital of Philadelphia announced the discovery of a unique genetic syndrome involving multiple congenital anomalies. The syndrome was named using the acronym CHOPS to describe its clinical characteristics: C—cognitive impairment and coarse facies (abnormal facial features), H—heart defects, O—obesity, P—pulmonary involvement, and S—short stature and skeletal dysplasia.

Genetic profile

CHOPS syndrome is extremely rare. It is caused by a mutation in the protein-coding portion of the *AFF4* gene.

Mutations in the *AFF4* gene interrupt the work of an important group of proteins called the super elongation complex (SEC). The SEC is an extremely important regulator in the process of transcription. In order for the genetic code within the DNA to be activated, it must first be transcribed or copied to RNA. During the process of transcription, DNA is copied to a type of RNA called messenger RNA (mRNA). The mRNA then goes through a process called translation in which it creates the proteins necessary to pass on the coded information from the DNA.

In humans, DNA is found almost exclusively within the nucleus of a cell. In order to express the traits contained in the DNA, the coded information must pass outside the cell's nucleus. RNA makes this possible because it can travel outside a cell's nucleus. Once the genetic material is copied to mRNA, it moves outside the nucleus of the cell, and it uses the copied information to produce proteins. mRNA passes on all information necessary for every part of an embryo to develop. It instructs cells to differentiate or become different cell types such as muscle, skin, or bone.

The SEC acts as the director of this process, signaling the mRNA when it is time to produce specific proteins. At each stage of fetal development, the SEC activates the mRNA. During the development of an embryo, this process is very sensitive and must be timed precisely in order for an embryo to develop into a fully formed typical fetus. If anything interrupts or delays this process at any point, it may disrupt normal fetal development.

When the SEC within the *AFF4* gene becomes abnormal through mutation, it causes abnormal proteins to be produced in every cell of the embryo. These abnormal proteins accumulate throughout the developing embryo, causing a cascade of abnormalities in other genes that are controlled by the *AFF4* gene.

This mutation is a random, or *de novo*, mutation. It is a germline mutation, meaning that it occurs in one of the individual egg or sperm cells that join to create the affected child. The mutation that causes CHOPS syndrome is a new mutation, not present in either parent but found in a single egg or sperm. Because of this, it is unlikely that subsequent children born to these parents will have the same mutation or develop CHOPS syndrome.

Demographics

In 2015, when CHOPS syndrome was first identified, there were three known cases. Researchers expected that more individuals with this syndrome would be identified as information about CHOPS syndrome became more widely known. A fourth case was reported in Korea in November 2020.

Signs and symptoms

The signs and symptoms of CHOPS syndrome include cognitive impairment, facial abnormalities, heart defects, obesity, pulmonary disorders, skeletal dysplasia, and short stature. These symptoms are similar to the features of Cornelia de Lange syndrome, a genetic disorder characterized by slow growth, intellectual disability, autistic-like behaviors, skeletal abnormalities of the arms and hands, unique facial features, heart defects, and short stature. However, the disorders are not identical. Differences between children with Cornelia de Lange syndrome and those diagnosed with CHOPS syndrome led researchers to investigate their genetic profiles. Over the course of ten years, researchers were able to identify three children with the previously unnamed disorder.

Cornelia de Lange syndrome is caused by a mutation in three genes. The children with CHOPS syndrome did not have any of these mutations. After years of investigating, scientists discovered the *AFF4* mutation. This groundbreaking discovery is the first example of a human developmental disorder caused by a mutation in the SEC.

Diagnosis

Diagnosis is made by clinical observation and identification of the features of CHOPS, which include developmental and intellectual delays, facial abnormalities, heart defects, obesity, pulmonary disorders, and skeletal dysplasia. In the presence of these clinical features, gene sequencing may be performed to determine whether there is a mutation in the *AFF4* gene.

In gene sequencing, a sample of blood or tissue is used to analyze the sequence or order of DNA in a person and to identify any specific abnormalities. In order to diagnose CHOPS syndrome, researchers studied the exomes, or regions in a gene that produce proteins. By studying these areas, they were able to identify the mutations responsible for CHOPS syndrome.

Treatment and management

CHOPS syndrome is a genetic disorder, and as of 2021, there was no cure. Management of the features, or symptoms, of the disorder is standard care.

Treatment of cognitive impairment and intellectual disability begins in early childhood and continues throughout adolescence and early adulthood. Early intervention educational programs may be especially helpful. Ongoing educational services and treatment involve a multidisciplinary team of professionals such as special educators, speech and language therapists, behavioral therapists, occupational therapists, and healthcare providers.

KEY TERMS

Congenital—A disorder or condition present at birth.

DNA (deoxyribonucleic acid)—A molecule within each cell that carries the genetic code for that organism.

Dysplasia—Abnormal development producing atypical shape or size.

Exome—The portion of a gene responsible for coding the instructions for protein production in the cell.

Gene sequencing—The process of mapping the order of DNA or genetic material in a cell or group of cells.

Germline mutation—A mutation or change in the DNA of a cell that will become either an egg or sperm.

Orthotics—A field of science that deals with the use of external mechanical devices to support or assist weak or abnormal joints, limbs, or muscles.

RNA (ribonucleic acid)—A molecule that assists in protein synthesis and gene expression.

Transcription—The process of making an RNA copy of genetic material.

Translation—The process of converting the sequence of messenger RNA into a series of amino acids in order to implement the genetic code of an organism.

Treatment of the medical conditions characteristic of CHOPS syndrome requires ongoing care from a team of healthcare providers. Complications from the associated heart defects and pulmonary disorders may lead to frequent hospitalizations.

The treatment of skeletal dysplasia and short stature is supportive. Medical care for these conditions involves preventing orthopedic and neurologic complications. Depending on the extent of the skeletal dysplasia, orthotics, assistive devices, and surgery may be necessary to improve mobility and decrease discomfort.

Because obesity can contribute to complications in individuals with skeletal dysplasia, it is important to address the accompanying obesity of CHOPS syndrome. Registered dietitians and physical therapists may help ensure that those with CHOPS syndrome have the proper nutrition and exercise they need to help reduce the impact of increased body weight.

QUESTIONS TO ASK YOUR DOCTOR

- What additional medical tests does a person with CHOPS syndrome need?
- What are the long-term effects of CHOPS syndrome?
- What special care does a person with CHOPS syndrome require?
- What other healthcare professionals should be consulted?
- Are there organizations or support groups to talk to other people whose children have this condition?
- Is there any information to take home?

Prognosis

Since there are so few known cases of CHOPS syndrome, the prognosis is not yet well determined. Each characteristic of CHOPS syndrome has a varying degree of risk associated with it; when combined, these risks may contribute to a shortened lifespan.

The prognosis for those with intellectual disability or cognitive impairment varies depending on the severity of the delays experienced by the individual. With successful early intervention and educational services, those with this condition alone may live long and productive lives.

Individuals with heart defects will require ongoing medical care and monitoring, and their prognosis will depend on the severity of the specific cardiac anomaly they have. However, early diagnosis of heart anomalies tends to lead to more effective treatment and a more positive prognosis.

The prognosis of those with the associated pulmonary disorders of CHOPS syndrome depends on the severity of the pulmonary conditions affecting the individual. Pulmonary disease can lead to frequent illness and hospitalizations, and it may shorten lifespan.

The prognosis of those with skeletal dysplasia depends on the severity of the skeletal abnormalities. Many people with skeletal dysplasia go on to live a normal lifespan. The associated obesity of CHOPS syndrome may negatively impact the health and comfort of individuals with more significant skeletal disorders.

As more children with CHOPS syndrome are identified, the long-term prognosis for this unique combination

of conditions and symptoms will be better understood and will become more predictable.

Chorionic villus sampling

Definition

Chorionic villus sampling (CVS) is a diagnostic test for genetic disorders in a fetus. It is performed between 10 and 12 weeks of gestation and involves sampling cells of the placental chorionic villi.

Purpose

CVS is a procedure that is commonly performed on pregnant women who are considered to be at risk for

having a baby with a genetic disorder. In particular, CVS may be offered to women aged 35 and older who are considered to be at greater risk for certain fetal genetic abnormalities, especially Down syndrome (trisomy 21)—an extra entire or partial chromosome 21. Down syndrome is by far the most common chromosomal abnormality. It occurs in approximately 1 in 700 births in the United States and causes physical and intellectual disabilities ranging from mild to severe. The risk of Down syndrome and certain other chromosomal abnormalities increases dramatically with increasing maternal age. Other candidates for CVS include the following:

- Women who have had a previous child or pregnancy affected by a birth defect
- Women who have had abnormal results on a maternal blood screening test for fetal abnormalities
- Women or women who have partners who have a genetic disorder or a family history of a genetic disorder, such as cystic fibrosis or sickle-cell disease
- Women or women who have partners who belong to an ethnic group with a high risk for certain genetic disorders

As of 2021, CVS could test for more than 200 genetic disorders. In addition to chromosome abnormalities, CVS can detect mutations (changes) in specific genes. In addition to Down syndrome, CVS is commonly used to test for inherited hemoglobinopathies, such as sickle-cell disease and Tay-Sachs disease, a serious genetic disorder of lipid (fat) metabolism that typically affects people of Eastern European Jewish ancestry. CVS also reveals whether the fetus is male (one X chromosome and one Y chromosome) or female (two X chromosomes). In addition to chromosome and DNA analyses for genetic defects, CVS may be able to detect the presence of bacteria and the concentration of metabolites.

Many pregnant women have diagnostic testing by amniocentesis, a procedure that withdraws from the womb a small amount of amniotic fluid containing fetal cells. The primary advantage of CVS over amniocentesis is that CVS is performed early in pregnancy—between 10 and 12 weeks (first trimester)—whereas amniocentesis is not performed until about 16 weeks of gestation (second trimester). This means that, in the unlikely case that an abnormality is discovered, the parents have more time to make decisions about whether to terminate the pregnancy, plan for caring for a child with a genetic disorder, or, in some cases, undergo fetal surgery or other treatment to alleviate the disorder.

Precautions

CVS is not offered to all pregnant women because it is an invasive procedure and there is a very small risk of miscarriage. Furthermore, the procedure itself—as well

A doctor holds an ultrasound emitter on a woman's pregnant abdomen while drawing a chorionic villus sample into a syringe. (Saturn Stills/Science Source)

as waiting for the results—can be stressful for some women, and CVS is more expensive than standard screening tests or amniocentesis. Therefore, CVS is only offered to women who are at increased risk of giving birth to a child with genetic abnormalities because of maternal age or other risk factors. Furthermore, CVS is not appropriate for all at-risk pregnant women. For example, many couples would not consider terminating a pregnancy even in the presence of serious or life-threatening fetal defects; others prefer not to know in advance that their child may have a genetic disorder.

CVS testing is not 100% accurate. For Down syndrome, the false-positive error rate is about 1% and the false-negative error rate is about 2%. In addition, CVS cannot test for all fetal abnormalities. For example, it does not detect neural tube defects (abnormalities in the formation of the brain and/or spinal column, such as spina bifida). Neural tube defects are detected by the presence of excess amounts of a protein called alpha-fetoprotein (AFP) in maternal blood serum or in amniotic fluid obtained via amniocentesis. CVS cannot detect Rh incompatibility, in which a mother who is negative for the Rh blood type may produce antibodies that attack an Rh-positive fetus, nor can CVS detect birth defects that occur during fetal development that are not due to genetic abnormalities or are caused by genetic abnormalities that cannot be—or were not—tested for.

As of 2021, new noninvasive and highly accurate screening tests were becoming available for conditions

such as Down syndrome. These tests can spare women invasive procedures such as CVS. They examine cell-free fetal DNA present in the mother's blood. At about ten weeks of gestation, approximately 10%–20% of the cell-free DNA in the mother's blood is fetal DNA from the placenta. These screening tests are performed late in the first trimester, but they can be performed as early as nine weeks. They are much more accurate and have far fewer false positives than the standard blood screening tests.

Ultrasound and the noninvasive screening tests that were typically offered to all pregnant women in 2015 are significantly less accurate than these newer tests, missing about 8% of Down syndrome cases, as well as yielding false-positive results that require women to subsequently undergo CVS or amniocentesis. The new tests are extremely accurate for Down syndrome, missing few if any affected fetuses and with false-positive results of less than 1%. The tests can also detect other genetic abnormalities, such as extra copies (trisomy) of chromosomes 13 and 18 or the absence of an X or Y sex chromosome. One new test is much better at predicting trisomy 18 than standard screening tests.

As of 2021, none of the new noninvasive tests had been approved by the U.S. Food and Drug Administration (FDA), and most had not yet undergone rigorous evaluation for effectiveness in clinical trials. Furthermore, the tests are quite expensive and not generally covered by insurance for women at low risk. Nevertheless, they may be recommended for women at high risk of having a baby with a chromosomal abnormality. These newer fetal DNA tests do miss some chromosomal abnormalities that can be detected with standard screening. They are also valid only for single-fetus pregnancies and are not diagnostic, so positive results for a chromosome abnormality still necessitates CVS or amniocentesis. However, studies of one new fetal DNA test suggest that it would reduce the number of women referred for CVS or amniocentesis by 90%. The American College of Obstetricians and Gynecologists and other professional societies have recommended these new-generation tests for women at higher risk for having a child with Down syndrome or another trisomy, but had not endorsed the tests for women at low risk.

Description

The chorion is the outermost fetal membrane that helps form the placenta, the organ formed by fetal and maternal tissues that provides nutrients and oxygen to the developing fetus and removes fetal waste products. The chorionic villi are finger-like folds in the chorion that contain capillaries where the fetal blood supply contacts

KEY TERMS

Amniocentesis—Prenatal testing performed at 16–20 weeks gestation by inserting a needle through the mother's abdomen and obtaining a small sample of amniotic fluid containing fetal cells for biochemical and/or DNA testing; an alternative to chorionic villus sampling.

Chorionic villi (singular, villus)—Finger-like folds in the early fetal membrane that partially forms the placenta; a source of fetal cells for genetic testing.

Cystic fibrosis—An inherited genetic disorder that affects many body systems, especially the lungs and digestive system.

Down syndrome—Trisomy 21, a genetic disorder caused by all or part of an extra chromosome 21; characterized by intellectual disability, characteristic facial features, and various other developmental defects.

Placenta—The organ that develops in the uterus during pregnancy and connects the mother's blood supply with that of the fetus.

Rh factor—Rhesus factor, a protein on the surfaces of red blood cells of many people; if the fetus is Rh-positive but the mother is Rh-negative, the mother must be treated with immune globulin to prevent the production of antibodies that will cross the placenta and attack the fetal blood cells.

Sickle-cell disease—An inherited disorder in which red blood cells contain an abnormal form of hemoglobin (the protein that carries oxygen), causing the cells to become sickle-shaped. The misshapen cells can clog blood vessels, preventing oxygen from reaching tissues.

Transabdominal CVS—Chorionic villus sampling performed using a needle inserted through the abdomen.

Transcervical CVS—Chorionic villus sampling performed using a catheter inserted through the vagina and cervix.

the maternal blood supply for the exchange of oxygen, nutrients, and waste. CVS removes a tiny amount of tissue from a chorionic villus. The tissue sample will contain fetal cells for testing. After about 12 weeks of gestation, the chorionic villi have formed the placenta, and CVS can no longer be performed. CVS was developed in the early 1980s and quickly became a widely performed procedure.

CVS is usually performed by a trained and experienced obstetrician or obstetrical surgeon. The doctor will be assisted by a nurse. A trained genetic counselor will be involved both before and after the procedure.

There are two types of CVS. Transabdominal CVS is performed by inserting a thin needle through the mother's abdomen into the uterus and chorionic villi. A small tissue sample is removed, and the needle is withdrawn. This procedure is very similar to amniocentesis. Transcervical CVS is performed by widening the vagina with a speculum and inserting a thin plastic tube (a catheter) through the mother's vagina and cervix (the opening to the uterus at the upper end of the vagina) to reach the chorionic villi. A tiny sample of tissue is then gently sucked through the tube, and the tube is removed from the uterus and vagina. Transabdominal or transcervical CVS is chosen according to the position of the fetus in the uterus.

The healthcare provider may also apply pressure to the mother's abdomen to determine the position of her uterus. With both types of CVS, ultrasound is used to guide the needle or tube to an appropriate area, and for removal of the tissue without harming the fetus. Ultrasound bounces harmless sound waves off fetal structures through a handheld device called a transducer, and the images formed are projected on a screen. A clear water-based gel is applied to the skin to facilitate the transmission of the sound waves as the transducer is moved over the area. Transcervical CVS may cause a feeling of pressure and some discomfort or cramping, similar to monthly periods or having a Pap test. Many women, however, find the procedure to be entirely painless. Once removed from the uterus, the tissue sample is placed in a dish and sent to a laboratory, where the chromosomes and DNA samples are removed from the fetal cells. The methods for handling the sample, examining the chromosomes, and testing for variants or mutations in specific genes depend on the type of technology used by the laboratory and the specific genetic tests to be performed. An entire CVS appointment, including preparation, may take 30–45 minutes, but the actual procedure takes only about 5 minutes.

Preparation

Women and their partners typically meet with a genetic counselor prior to deciding to have CVS. The counselor will inquire about any history of genetic disorders in the families of both parents to assess the need for CVS and any specific genetic tests that should be performed. Choosing to undergo CVS is a personal decision for each woman, and genetic counselors, as well as other healthcare providers and religious or spiritual counselors, can help a woman and her partner decide whether to

QUESTIONS TO ASK YOUR DOCTOR

- Should I have chorionic villus sampling because I am over age 35?
- What risk factors would indicate the need for chorionic villus sampling?
- Do you recommend that my partner and I meet with a genetic counselor?
- What are the advantages and risks of chorionic villus sampling compared with amniocentesis?
- Are there blood screening tests available that could be used instead of chorionic villus sampling?

proceed. The woman's healthcare provider will explain the CVS procedure, risks, and alternatives.

Women undergoing CVS are told to drink fluids and not urinate on the morning of the procedure so that the bladder is full during the procedure. This helps the physician determine where to place the needle. The woman will be asked about allergies to iodine, shellfish, or other substances. She signs a consent form for CVS and changes into a hospital gown. Women who are Rh-negative and unsensitized are given Rh immune globulin (RHIG or RhoGAM) at the time of the CVS to prevent complications of Rh incompatibility.

Aftercare

Women should relax for the remainder of the day after CVS. They may have spotting (a small amount of vaginal bleeding) or cramping for a few hours. Women should call their healthcare provider immediately if they experience heavy bleeding, fever, or contractions following CVS. A follow-up ultrasound will be performed two to four days after CVS to ensure that the pregnancy is proceeding normally.

Risks

The risks of CVS are only slightly higher than the risks of amniocentesis. There is a 1% risk of miscarriage following CVS. Miscarriage rates with transcervical CVS are slightly higher than with transabdominal CVS. Other possible complications include bleeding, infection, rupture of the membranes surrounding the fetus, or Rh incompatibility in the mother if this was not detected previously. There is a very slight risk of causing the loss of fingers or toes of the fetus, other limb abnormalities, or

defects in the jaw or tongue, but only if CVS is performed too early—before nine weeks of gestation.

Results

Results of the tests on cells obtained by CVS are typically available in one to two weeks. The test results are usually normal, indicating that the baby is healthy and without genetic abnormalities, even when results were positive with a maternal blood screening test. However, testing may not detect some genetic abnormalities. In the rare instances in which a genetic abnormality is detected, the healthcare provider will explain the results and discuss options with the parents. Some genetic abnormalities can be treated with medications or surgery before or after birth. Early knowledge of a birth defect can help the parents and healthcare providers plan for the baby's birth. Early knowledge can also help emotionally prepare parents to care for a newborn with special needs and ensure that the baby receives medical care immediately upon birth. In cases of severe birth defects, women may decide to terminate the pregnancy.

Although the laboratory results will indicate the baby's sex, it is up to the parents whether they want to know whether their child is male or female. Many people prefer to wait until the baby is born.

Choroideremia

Definition

Choroideremia is a rare genetic disorder causing progressive eyesight loss due to the wasting away of retinal layers. It first affects the choroid and the retinal pigmented epithelium (RPE) layers and finally the photoreceptor cell layer. Atrophy (wasting) of the optic nerve is also observed in choroideremia.

Description

Formerly called tapetochoroidal dystrophy, choroideremia is a chronic form of retinal disease characterized by degeneration of the layers of the retina, which is the light-sensitive part of the eye. There are four main retinal layers: the outer neural retina, consisting of nerve cells and blood vessels; the retinal pigment epithelium (RPE); the choroid layer that contains connective eye tissue and a capillary layer (chorio capillaris); and the photoreceptor (light-sensitive) layer that contains the rods and cones, which function as detectors to process light, color, and shape signals to the brain. Choroideremia is a progressive disease, meaning that the layers become affected one after the other over time.

The pigmentary changes in the RPE begin with fine spotting and continue with areas of depigmentation and increasing loss of the chorio capillaris. Chorio capillaris loss and degeneration of the larger choroidal blood vessels cause areas of bare sclera. The sclera is the tough white fibrous tissue that covers the "white" of the eye. The disease begins in mid-periphery of the choroid, but then progresses to include the entire choroid.

Choroidal vessels provide oxygen and nutrients to both the RPE and the retina's photoreceptor cells. The RPE, which lies directly beneath the retina, supports the function of photoreceptor cells. Photoreceptor cells (rods and cones) convert light into the electrical impulses that transfer messages to the brain where seeing actually occurs. In the early stages of choroideremia, the choroid and the RPE begin to deteriorate. Eventually,

photoreceptor cells also degenerate, resulting in a loss of central vision.

The age at which choroideremia first appears varies; initial symptoms (usually night blindness) may occur as early as three years of age and as late as forty years. However, occurrence peaks between the ages of ten and forty. The visual field becomes progressively constricted, and patients usually reach legal blindness by twenty-five years of age. Loss of central vision usually occurs after the age of thirty-five. However, in most patients with choroideremia, visual acuity (acuteness or sharpness of vision) is well maintained until the late stages of the disease.

Genetic profile

Choroideremia is an X-linked disorder, or a condition that is transmitted on the X chromosome. Females have two X chromosomes; males have an X and a Y chromosome. Thus in females, the altered gene on one X chromosome can be masked by the normal gene on the other X chromosome. Female carriers—who may or may not be symptomatic—have a 50% chance of passing the X-linked abnormal gene to their daughters, who become carriers; and a 50% chance of passing the gene to their sons, who are then affected by the disease.

In most individuals, choroideremia is caused by mutations (pathogenic variations) in the *CHM* gene and affected individuals display only disease-related ocular symptoms. However, in very rare cases, a small number of males have a chromosome deletion on their X-chromosome (at Xq21) involving the *CHM* gene. Depending on the size of this deletion, affected males can have associated hearing loss, birth defects, and varying degrees of intellectual disabilities. In these individuals, the mothers are the carriers, showing the same deletions but not the severe clinical manifestations.

Demographics

Choroideremia is believed to affect approximately 1 in 50,000 individuals—primarily men—although women who are carriers may exhibit mild symptoms as well. In an area of northern Finland (the Sala region) about 1 in 40 people have the disorder, due to inheritance of a single mutation from common ancestors (founder effect).

Signs and symptoms

Choroideremia is characterized by extensive abnormalities in the RPE layer. The initial symptoms include wasting of the retinal layers and choroid of

KEY TERMS

Choriocapillaris—Capillary layer of the choroid.

Choroid—A vascular membrane that covers the back of the eye between the retina and the sclera and serves to nourish the retina and absorb scattered light.

Electroretinogram (ERG)—A measurement of electrical activity in the retina.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Retinal pigment epithelium (RPE)—The pigmented cell layer that nourishes the retinal cells; located just outside the retina and attached to the choroid.

Retinitis pigmentosa—Progressive deterioration of the retina, often leading to vision loss and blindness.

the eye. The choroid (the vascular membrane located between the retina inside the eye and the sclera) contains large branched pigmented cells and prevents light rays from passing through areas of the eye outside of the pupils. Night blindness is usually the first noticeable symptom of choroideremia, usually occurring during childhood.

Because the diffuse, progressive atrophy of the chorio capillaris and RPE layers begins peripherally and spreads centrally, central macular function (central vision) is preserved until late in the course of the disease. Myopia occurs more frequently in men diagnosed with choroideremia. Although symptoms vary widely among affected individuals, men usually retain little or no useful vision beyond the age of 60.

Degeneration of the vessels of the choroid and functional damage to the retina occur later in life and usually lead to progressive central vision field loss and eventual blindness. Small bony-like formations and scattered pigment clumps tend to accumulate in the middle portion and on the edges of the choroid. In addition, color vision is initially normal but may later evolve into tritanopia (color blindness in which there is an abnormality in the perception of blue).

Female carriers usually have no symptoms and have normal visual fields, normal visual acuity, and normal electroretinograms (a measurement of electrical activity of the retina). However, female carriers sometimes show abnormalities of the interior lining of the eye in the form of pigment spotting with tiny patches of RPE depigmentation. Brownish granular pigmentation and changes in

QUESTIONS TO ASK YOUR DOCTOR

- A cousin was recently diagnosed with choroideremia. Does the disorder run in families?
- What are the chances that my future children might inherit the disorder?
- What are the primary features of the disorder?
- At what age do the symptoms of choroideremia first manifest themselves?
- What kinds of treatment are available for this disorder?

the RPE and choroid may occur later. There is also some evidence to suggest that mild progression of symptoms—and even the full disease—may occur in a small number of female carriers.

A variety of other degenerations of the choroid may look like choroideremia. Some abnormalities seen in the early stages of the disorder are symptoms also seen in other genetic vision disorders causing retinal degeneration, such as X-linked retinitis pigmentosa. However, unlike retinitis pigmentosa, which starts in early childhood, the onset of choroideremia is variable and is rarely seen in childhood. The distinguishing feature of choroideremia is the diffuse choroidal atrophy that is uncommon in early retinitis pigmentosa.

Diagnosis

Individuals with other disorders (hearing loss, intellectual disabilities) in addition to choroideremia should be tested for DNA deletions. Chromosome microarray, a DNA testing technique that detects deletions, should be the first test performed.

For individuals of Finnish ancestry with choroideremia, targeted mutation analysis for the mutations found in this population is done first.

If the DNA mutation in a family is known, prenatal diagnosis for choroideremia can be done. All family members with a history of choroideremia are encouraged to consult an ophthalmologist and to seek genetic counseling. These professionals can explain the disease and the inheritance risk for all family members and for future offspring.

Treatment and management

Although there is currently no treatment, choroideremia is a disease that has been shown to be a prime

candidate for the development of an effective gene therapy. As of 2021, numerous research studies were evaluating various methods of gene therapy and stem cell therapies. The goal of these therapies is to repair the gene mutation in the eyes and generate working REP-1 protein.

Assistance for individuals with choroideremia is available through low-vision aids, including optical, electronic, and computer-based devices. Personal, educational, and vocational counseling, as well as adaptive training skills, are also available through community resources. Additionally, some physicians recommend nutritional therapy including fresh fruits and vegetables, an antioxidant supplement, and omega-3 fatty acids from fish or supplements. Protecting the eyes from UV light (sunlight) by use of sunglasses or other means is also advised.

Prognosis

Progression of the disease continues throughout the individual's life, although both the rate and degree of visual loss are variable among those affected, even within the same family.

Chromosomal abnormalities

Definition

Chromosomal abnormalities describe changes in the normal number of chromosomes or structural problems within the chromosomes themselves. They are also called chromosomal aberrations or anomalies. There are two basic categories: numerical, in which there are an abnormal number of chromosomes; and structural, in which a portion of the chromosome's structure is missing, duplicated, translocated, or otherwise changed.

Chromosomal abnormalities occur when a gamete (sex cell; egg or sperm) with an incorrect number of chromosomes or a structurally faulty chromosome unites with a normal egg or sperm during conception. Some chromosomal abnormalities occur shortly after conception. In this case, the zygote, the cell formed during conception that eventually develops into an embryo, divides incorrectly.

Chromosomal abnormalities can cause serious mental or physical disabilities. Down syndrome, for instance, is caused by an extra chromosome 21. People with Down syndrome have some degree of intellectual disability and may have a host of physical problems, including heart disorders. Other individuals with Down syndrome *mosaics* have a mixture of normal cells and cells with three copies of chromosome 21, resulting in a milder form of the disorder. Most abnormalities in chromosome number lead to the death of the embryo. Zygotes that receive a full extra set of chromosomes, a condition called polyploidy, usually do not survive inside the uterus and are spontaneously aborted (a process sometimes called a miscarriage).

Normal number and structure of human chromosomes

A chromosome consists of the body's genetic material, the deoxyribonucleic acid, or DNA, along with many

kinds of proteins. Within the chromosomes, the DNA is tightly coiled around these proteins (called histones) allowing approximately 6-foot-long (2 m) strands of DNA to occupy a microscopic space within the nucleus of the cell. When a cell is not dividing, the chromosomes are invisible within the cell's nucleus. Just prior to cell division, the chromosomes begin to replicate and condense. As the replicated DNA condenses, each chromosome looks somewhat like a fuzzy "X" under the microscope. Chromosomes contain the genes (segments of DNA that code for proteins) of an individual. When a chromosome is structurally faulty, or when a cell contains an abnormal number of chromosomes, the types and amounts of the proteins encoded by the genes are changed. When proteins are altered in the human body, the result can be serious mental and physical disorders or disease.

Humans have 46 chromosomes—22 pairs of autosomal chromosomes (also called autosomes) and one pair of sex chromosomes. These chromosomes may be examined by constructing a karyotype, or organized depiction, of the chromosomes. To construct a karyotype, a technician stops cell division just after the chromosomes have replicated using a chemical like colchicine. The chromosomes are visible within the nucleus at this point. The image of the chromosomes seen through the microscope is photographed. Each chromosome is cut out of the picture and arranged on another sheet in the correct sequence and orientation. The resultant image is called a karyogram. The chromosome pairs are identified according to size, shape, and characteristic stripe patterns (called banding).

Chromosomal abnormalities chart (Gale)

Normal cell division

In most animals, two types of cell division take place: mitosis and meiosis. In mitosis, each cell division produces two cells that are identical to the parent cell; i.e., one parent cell produces two daughter cells. Compared to its parent chromosome, each daughter cell has exactly the same number of chromosomes and identical genes. This preservation of chromosome number and structure is accomplished through the replication of the entire set of chromosomes just before mitosis.

Sex cells (eggs and sperm) undergo a different type of cell division called meiosis. Because sex cells each contribute half of a zygote's genetic material, sex cells must carry only half the full number of chromosomes. This reduction in the number of chromosomes within sex cells is accomplished during two rounds of cell division, called meiosis I and meiosis II. Before meiosis I, the chromosomes replicate. During meiosis I, a cell with 46 replicated chromosomes divides to form two cells that each contain 23 replicated chromosomes. Normally, the meiosis I division separates the 23 pairs of chromosomes evenly, so that each daughter cell contains one chromosome from each chromosome pair. No replication occurs between meiosis I and meiosis II. During meiosis II, the two daughter cells containing 23 replicated chromosomes divide to form four daughter cells, each containing 23 non-replicated chromosomes. Mistakes can occur during either meiosis I or meiosis II. Chromosome pairs may fail to separate during meiosis I, or a replicated chromosome may fail to separate during meiosis II.

Meiosis produces four daughter cells, each with half the normal number of chromosomes. These sex cells are called haploid cells (haploid means "half the number"). Non-sex cells in humans are called diploid (meaning "double the number") since they contain the full number of normal chromosomes. Human diploid cells normally each have 46 chromosomes, and haploid cells normally each have 23 chromosomes.

Alterations in chromosome number

Two kinds of chromosome number alterations can occur in humans: aneuploidy, an abnormal number of chromosomes; and polyploidy, more than two complete sets of chromosomes.

Aneuploidy

Most alterations in chromosome number occur during meiosis. During normal meiosis, chromosomes are distributed evenly among the four daughter cells. Sometimes, however, an uneven number of chromosomes is distributed to the daughter cells. As noted in the previous section, chromosome pairs may not move apart in meiosis I, or the chromosomes may not separate in

Chromosome 1 (Gale)

meiosis II. The result of both kinds of mistakes (called nondisjunction of the chromosomes) is that one daughter cell receives an extra chromosome and another daughter cell does not receive any chromosome.

When an egg or sperm that has undergone faulty meiosis and has an abnormal number of chromosomes unites with a normal egg or sperm during conception, the zygote formed will have an abnormal number of chromosomes. This condition is called *aneuploidy*. There are several types of aneuploidy. If the zygote has an extra chromosome, the condition is called *trisomy*. If the zygote is missing a chromosome, the condition is called *monosomy*.

If the zygote survives and develops into a fetus, the chromosomal abnormality is transmitted to all of its cells. The child that is born will have symptoms related to the presence of an extra chromosome or absence of a chromosome.

Examples of aneuploidy include trisomy 21, also known as Down syndrome, and trisomy 13, also called Patau syndrome. Trisomy 13 occurs in 1 out of every 5,000 births. Its symptoms are more severe than those of Down syndrome. Children with trisomy 13 always have severe physical and brain malformations and often have cleft palate and eye defects. Trisomy 18, known as Edwards syndrome, results in severe multiple defects. Children with trisomy 13 and trisomy 18 usually survive less than a year after birth.

Aneuploidy of sex chromosomes

Sometimes nondisjunction occurs in the sex chromosomes. Humans have one set of sex chromosomes. These sex chromosomes are called “X” and “Y” after their approximate shapes in a karyotype. Males have both an X and a Y chromosome, while females have two X chromosomes. Disorders associated with abnormal numbers of sex chromosomes are less severe than those associated with abnormal numbers of autosomes. This is thought to be because the Y chromosome carries few genes and the extra X chromosomes are inactivated shortly after conception. Nevertheless, aneuploidy in sex chromosomes causes changes in physical appearance and in fertility.

Individuals with Klinefelter syndrome, for instance, are men with two X chromosomes (XXY). This condition occurs in 1 out of every 600 male births. Men with Klinefelter syndrome have small testes and are usually sterile. Some men with Klinefelter develop enlarged breasts (gynecomastia). Males who are XXY are of normal intelligence. However, intellectual disabilities are not unusual in males with more than two X chromosomes, such as XXXY, XXXXY, or XXXXXY.

Males with an extra Y chromosome (XYY) have no physical defects, although they may be taller than average. XYY males occur in 1 out of every 1,000 male births.

Chromosomal abnormalities chart (Gale)

Females with an extra X chromosome (XXX) are sometimes said to have triple X syndrome and were sometimes called metafemales. This defect occurs in 1 out of every 1,000 female births. Females with XXX do not usually have any intellectual disability; their pubertal development and fertility are normal.

Females with only one X chromosome (XO) have Turner syndrome. Turner syndrome is also called monosomy X and occurs in 1 out of every 2,000–5,000 female

Klinefelter's syndrome	XXY
Extra Y	XYY
Metafemale	XXX
Turner's syndrome	XO

Chromosomal abnormalities in various syndromes (Gale)

births. The sex organs of females with Turner syndrome do not mature at puberty. Therefore, these women are usually sterile. They are of short stature and have no mental deficiencies. Heart defects are more common in girls with Turner syndrome.

Polyploidy

Polyploidy is lethal in humans. Normally, humans have two complete sets of chromosomes. Normal human cells other than sex cells are thus described as diploid. In polyploidy, a zygote receives more than two complete chromosome sets. Examples of polyploidy include triploidy, in which a zygote has three sets of chromosomes, and tetraploidy, in which a zygote has four sets of chromosomes. Triploidy may result from the fertilization of an abnormal diploid sex cell with a normal sex cell or from the fertilization of one egg by two sperm. Tetraploidy could result from the failure of the zygote to divide after it replicates its chromosomes. Human zygotes with either of these conditions usually die before birth or soon after. Interestingly, polyploidy is common in plants and is essential for the proper development of certain stages of the plant life cycle. Also, some kinds of cancerous cells have been shown to exhibit polyploidy.

Alterations in chromosome structure

Another kind of chromosomal abnormality is any change of chromosome structure. Structural defects arise during replication of the chromosomes just before a meiotic cell division. Meiosis is a complex process that often

involves the chromosomes exchanging segments with each other in a process called crossing-over. If the process is faulty, the structure of the chromosome changes. Sometimes these structural changes are harmless to the zygote. Other structural changes, however, can be lethal.

Six types of general structural alterations occur during replication of chromosomes. All six types begin with the breakage of a chromosome during replication. In a deletion, the broken segment of the chromosome is lost. Thus, all the genes that are present on this segment are also lost. In an insertion, the segment deleted from one chromosome is implanted into a different chromosome instead of being lost altogether. In duplication, the segment is inserted into the homologous chromosome as extra (duplicated) DNA. In an inversion, the broken segment reattaches to the original chromosome but is reversed end to end. In a translocation, the segment attaches to an entirely different chromosome. In a ring, a portion of the chromosome breaks off and the ends join to form a circle or ring. The ring type of structural alteration may occur with or without the loss of genetic material.

Because chromosomal structural changes cause the loss or misplacement of genes, the results can be quite severe. Deletions and duplications lead to missing or extra chromosomal material, meaning that there are too many or too few genes in that region. Translocations may or may not be harmful. If the translocation is balanced, meaning that all DNA is present and none is missing, the only effect may be a higher risk of abnormal sperm or eggs. If the translocation is not balanced, the chance of associated physical and cognitive abnormalities increases. Inversions of DNA may also be harmless except for a risk of abnormal sperm or eggs. However, both inversions and balanced translocations may have clinical consequences, depending on where the breakage and rejoining of DNA occurred.

A structural abnormality in chromosome 21 occurs in about 4% of people with Down syndrome. In this abnormality—a translocation—a piece of chromosome 21 breaks off during meiosis of the egg or sperm cell and attaches to chromosomes 13, 14, or 22. The parents of a child with Down syndrome due to this type of translocation could be balanced carriers for the translocation, and if so, are at increased risk of having another child with Down syndrome.

Some structural chromosomal abnormalities have been implicated in certain cancers. For instance, myelogenous leukemia is a cancer of the white blood cells. Researchers have found that the cancerous cells contain a translocation of chromosome 22, in which a broken segment switches places with the tip of chromosome 9.

Syndromes associated with chromosomal deletions

Many syndromes are associated with chromosomal deletions. These include cri du chat syndrome, velocardiofacial syndrome, Prader-Willi syndrome, Angelman syndrome, Wolf-Hirschhorn syndrome, Smith-Magenis syndrome, Miller-Dieker syndrome, Langer-Giedion syndrome, and the trichorhinophalangeal syndromes.

Cri du chat means “cat’s cry” in French. Children with this syndrome have an abnormally developed larynx that makes their cry sound like the meowing of a cat in distress. They also have a small head, misshapen ears, and a rounded face, as well as other systemic abnormalities and intellectual disability. Cri du chat syndrome is caused by a deletion of a segment of DNA in chromosome 5.

Velocardiofacial syndrome is also called DiGeorge syndrome or Shprintzen syndrome. More recently, it has been called deletion 22q11 syndrome because it is caused by a deletion of part of chromosome 22. Individuals with velocardiofacial syndrome may have congenital heart disease, cleft palate, learning difficulties, and subtle characteristic facial features.

Two syndromes caused by a chromosome abnormality illustrate an interesting concept: The severity or type of symptoms associated with a chromosomal defect may depend upon whether the child receives the changed gene from the mother or the father. Both Prader-Willi syndrome and Angelman syndrome are usually caused by a deletion in chromosome 15. Prader-Willi syndrome is characterized by intellectual disability, obesity, short stature, and small hands and feet. Angelman syndrome is characterized by jerky movements and neurological symptoms. People with this syndrome also have an inability to control laughter; they may laugh inappropriately at odd moments. If a child inherits the changed chromosome from its father, the result is Prader-Willi syndrome. However, if the child inherits the changed chromosome from its mother, the child will have Angelman syndrome.

A person may have Prader-Willi or Angelman syndrome without the chromosomal deletion usually associated with these conditions, due to a chromosomal error called uniparental disomy. Usually, one of each chromosome pair is inherited from each parent. Usually, every section of DNA has two copies—one maternally inherited and the other paternally inherited. Uniparental disomy refers to the mistake of both copies of a section of DNA being inherited from one parent. Two copies of a maternally inherited chromosome 15 (no paternal gene present) causes Prader-Willi syndrome, and two copies of a paternally inherited chromosome 15 causes Angelman syndrome.

The sequence of events leading to Prader-Willi and Angelman syndrome is unknown. Researchers have determined that the genes in this region on chromosome 15 may be “turned off,” depending on which parent contributed the chromosome. This process of gene inactivation is called imprinting. Some people have both Prader-Willi and Angelman syndrome because the mechanism controlling the imprinting malfunctions.

Expansion of chromosomal material

Not only can the sex of the parent from whom a gene is inherited determine whether it is “turned on” or “turned off,” but the sex of the parent may also influence whether certain abnormal sections of chromosomes become more abnormal. For example, the sex of the parent contributing the X chromosome may increase or decrease the chance that a child will be affected with fragile X syndrome.

Fragile X syndrome occurs in 1 out of 1,000 male births and 1 out of 2,000 female births. Males are affected more severely than females and the syndrome may be more pronounced if the child inherits the disorder from his/her mother. This difference is explained by the fact that fragile X syndrome is caused by an abnormality of the X chromosome. Remember that a male is XY and a female is XX. A male child receives a Y chromosome from the father and an X chromosome from the mother. A female child, however, can receive an X from either the mother or the father. Girls with fragile X syndrome are less severely affected than boys because they have a normal X chromosome that helps to protect them from the abnormal X chromosome. However, it was somewhat perplexing to researchers that girls are affected at all.

This mystery was solved when researchers learned that there is a range of abnormality in the fragile X chromosome. If the abnormality of the fragile X region of the chromosome is severe, the influence can be strong enough to affect females. If the abnormality is mild, females will not have symptoms of fragile X syndrome. Furthermore, the fragile X region of the X chromosome may become more severe when it is maternally inherited. The sex of the parent that the region is inherited from affects whether the chromosome abnormality remains stable or becomes greater.

Many other conditions are associated with similar chromosomal abnormalities and may remain stable or become more severe depending upon whether the chromosome region is inherited from the mother or the father. In some of these conditions, the region becomes more abnormal when it is paternally inherited. Huntington’s disease, an adult-onset neurological disease, is one such condition.

KEY TERMS

Aneuploidy—A condition in which the number of chromosomes in the nucleus of a cell is abnormal.

Autosomal chromosome—Any chromosome that is not a sex chromosome. Autosomal chromosomes are also called autosomes.

Chromosome—A packaged and organized structure containing most of the DNA of a living organism.

Chromosome microarray analysis (CMA)—A computerized technique that compares a patient's DNA with control DNA to identify clinically significant chromosomal abnormalities below the resolution level of conventional chromosome analysis.

Deletion—A mutation in which part of a chromosome or a sequence of DNA is missing.

Duplication—A mutation in which part of the chromosome is repeated, adding extra genetic material.

Gamete—A cell that fuses with another cell during fertilization in organisms that reproduce sexually. Gametes carry half of an individual's genetic information. They are formed through the process of meiosis.

Histones—Alkaline proteins found in cell nuclei that act as spools for winding strands of DNA, allowing the DNA to be stored compactly within the cell nucleus.

Insertion—A mutation in which part of a chromosome is deleted from its normal location and implanted into another chromosome.

Inversion—A rearrangement of genetic material within a chromosome that occurs when a portion of the chromosome breaks off, is reversed end to end, and is reattached.

Karyotype—The complete set of chromosomes in a species, or in a specific individual of that species. The chromosomes are depicted in a standard format known as a karyogram.

Meiosis—A specialized form of cell division in which DNA replication is followed by two rounds of cell division to produce four daughter cells with half the number of chromosomes as the parent cell. The two rounds of cell division are known as meiosis I and meiosis II.

Mitosis—The division of a cell into two identical daughter cells that are genetically identical to each other and to the parent cell.

Monosomy—A type of aneuploidy in which a cell contains only one copy of a chromosome rather than the normal two.

Mosaicism—A condition resulting from abnormal chromosome division, such that the organism contains different types of cells with different numbers of chromosomes.

Ploidy—The number of sets of chromosomes in the nucleus of a cell.

Point mutation—A mutation within a DNA or RNA molecule that involves a change in only one nucleotide base. It is also known as a single base substitution.

Polyploidy—A condition in which the nucleus of a cell contains more than two paired sets of chromosomes.

Ring—A structural chromosomal abnormality in which a portion of a chromosome breaks off and its ends join to form a circle or ring. There may or may not be loss of genetic material in a ring chromosome.

Translocation—A mutation in which a portion of a chromosome is transferred to another chromosome.

Trisomy—A type of aneuploidy in which there are three copies of a given chromosome instead of the normal two.

Zygote—The cell formed when sperm and egg are joined during the process of sexual reproduction.

Maternal and paternal age-related abnormalities

Currently, no cures exist for any of the syndromes caused by chromosomal abnormalities. For most of the conditions caused by aneuploidy, the risk of giving birth to a child with a chromosomal abnormality increases with the mother's age. The risk of Down syndrome, for instance, jumps from 1 in 1,000 when the mother is age

15–30 to 1 in 350 at age 35. This risk is most likely because the risk for nondisjunction as the eggs finish forming increases as maternal age increases. A man's age increases the nondisjunction risk slightly because of differences in the way eggs and sperm develop. Sperm mature and reproduce throughout a man's adult life. However, older men are more likely than younger men to have mutations occur during spermatogenesis. Women, on the other hand, are born with all the eggs they

will ever have. At birth these eggs are part way through meiosis I, and each month as a woman ovulates one egg finishes meiosis I and begins meiosis II.

Genetic testing and diagnosis

People at high risk of chromosomal abnormalities may opt to know whether the fetus they have conceived has one of these abnormalities. There are several methods of prenatal screening and testing as of 2021, as well as testing infants and children after birth for chromosomal abnormalities.

Amniocentesis and chorionic villus sampling

Amniocentesis is a procedure in which some of the amniotic fluid that surrounds and cushions the fetus in the uterus is sampled with a needle placed in the uterus. Real-time ultrasound is used to guide the procedure. The amniotic fluid contains fetal cells that can be tested for chromosomal, DNA, and biochemical abnormalities. Another test, chorionic villus sampling (CVS), involves taking a piece of tissue from the developing placenta. Undergoing either amniocentesis or CVS increases the risk of miscarriage slightly. Women and couples considering the procedure should be fully informed of the risks, benefits, and limitations of each procedure. If an abnormality is detected, the prenatal care provider discusses the options available with the woman or couple. Chromosomal abnormalities cannot be corrected. Some parents may choose to terminate the pregnancy. Other parents choose to continue the pregnancy and use the time to prepare for the birth of a child with special needs.

Chromosome microarray analysis

Chromosome microarray analysis (CMA) is a newer technique that has been in use since the early 21st century. It allows screening to identify gains and losses of DNA across the entire human genome. CMA can detect chromosomal abnormalities below the level of conventional karyotyping. To perform CMA, a laboratory technician extracts DNA from a sample of fetal tissue obtained by amniocentesis or chorionic villus sampling, and then hybridizes it onto a glass slide containing a large number (as many as two million) of molecular probes. The probes represent control DNA derived from a person without any chromosomal abnormalities. The prepared slide is then scanned by a computer to identify copy number variants (CNVs). CNVs include microduplications or microdeletions too small to be seen under a microscope; most abnormalities of chromosome number (trisomies and monosomies); most unbalanced rearrangements of chromosome structure; and some forms of mosaicism. The advantage of CMA is that it can detect unexpected chromosomal abnormalities as well as suspected CNVs.

CMA has some limitations as well as advantages. First, it can detect abnormalities of unknown clinical significance, thus adding to parental anxiety. Second, CMA cannot detect all genetic disorders. It does not, for example, detect point mutations (small changes within the sequence of a single gene) or balanced chromosomal rearrangements (balanced translocations or inversions).

CMA can be used for either prenatal or postnatal analysis. Prenatal CMA is usually undertaken after an ultrasound examination indicates the presence of fetal abnormalities. As of 2021, however, CMA is more often used to evaluate infants or children who display any abnormal characteristics but do not fit a known genetic syndrome. Some of the characteristics that would suggest CMA testing include developmental delays, multiple congenital abnormalities, intellectual impairment, or autism spectrum disorders. Parents should plan for a consultation with a geneticist before and after CMA testing in order to understand the results of the test and to determine whether further genetic testing (of the child or of other family members) may be advisable.

Many resources are available to parents learning of abnormalities before or after birth. In the case of a sex chromosome abnormality, it is common for people to learn of the abnormality as a teenager or even as an adult. A primary care physician, obstetrician, or support group can recommend a specialist offering more information. This specialist is often a medical geneticist, perinatologist, or genetic counselor. Many organizations also provide resources and information to individuals and families.

In conclusion, the division of chromosomes during development and during sperm and egg formation is a complex process. Most of the time, however, the process occurs normally. Mistakes that are made can result in changes in chromosome number as well as abnormal chromosomes. Extra or missing chromosomal material usually leads to physical and cognitive defects. Changes in sex chromosome complement are often associated with milder problems. Some problems with chromosomes are relatively common and are associated with well-defined syndromes. Other problems with chromosomes occur rarely and problems associated with the change are seen in only a few individuals.

Chromosome

Definition

Chromosomes are microscopic units containing organized genetic information that are located in the nuclei of diploid and haploid cells (for example, human somatic and sex cells), and are also present in one-cell nonnucleated organisms (unicellular microorganisms),

like bacteria, which do not have an organized nucleus. The sum total of genetic information contained in different chromosomes of a given individual or species is generically referred to as the genome.

Description

In humans, chromosomes are structurally made of roughly equal amounts of proteins and DNA. Each chromosome contains a double-strand DNA molecule arranged as a helix and tightly coiled and neatly packed by a family of proteins called histones. DNA strands are composed of linked nucleotides. Each nucleotide has a sugar (deoxyribose), a nitrogenous base, and one to three phosphate groups. Each nucleotide is linked to adjacent nucleotides in the same DNA strand by phosphodiester bonds. Nucleotides of one DNA strand link to their complementary nucleotide on the opposite DNA strand by hydrogen bonds, thus forming a pair of nucleotides, known as a base pair or nucleotide base. Genes contain up to thousands of sequences of these base pairs. What distinguishes one gene from another is the sequence of nucleotides that code for the synthesis of a specific protein or portion of a protein. Some proteins are necessary for the structure of cells and tissues. Others, like enzymes—a class of active (catalyst) proteins—promote essential biochemical reactions, such as digestion, energy generation for cellular activity, or metabolism of toxic compounds. Some genes produce several slightly different versions of a given protein through a process of alternate transcription of base pair segments known as codons.

Numbers of autosomal chromosomes differ in cells of different species but are usually the same in every cell of a given species. Sex determination cells (mature ovum and sperm) are an exception, where the number of chromosomes is halved. Chromosomes also differ in size. For instance, the smallest human chromosome, the sex chromosome Y, contains 57 million base pairs (bp), whereas the largest one, chromosome 1, contains 249 million base pairs. All three billion base pairs in the human genome are stored in 46 chromosomes. Human genetic information is therefore stored in 23 pairs of chromosomes (totaling 46); 23 inherited from the mother, and 23 from the father. Two of these chromosomes are sex chromosomes (chromosomes X and Y). The remaining 44 are autosomes, meaning that they are not sex chromosomes and are present in all somatic cells (i.e., any other body cell that is not a germinal cell for spermatozoa in males or ova in females). Sex chromosomes specify the offspring's sex: normal females have two X chromosomes, and normal males have one X and one Y chromosome.

Each set of 23 chromosomes constitutes one set of alleles, containing gene copies inherited from one of the progenitors. The other allele is complementary, or homologous, meaning that it contains copies of the same genes

Normal human karyotype. (Capreola/Shutterstock.)

and on the same positions, but originated from the other parent. As an example, every normal child inherits one copy of gene *BRCA1*, located on chromosome 17, from the mother, and another copy of *BRCA1* from the father, located on the other allelic chromosome 17. “Allele” is a Greek-derived word that means “one of a pair,” or any one of a series of genes having the same locus (position) on homologous chromosomes.

The first chromosome observations were made under light microscopes, revealing rod-shaped structures in varied sizes and conformations commonly J- or V-shaped in eukaryotic cells and ring-shaped chromosomes in bacteria. Staining reveals a pattern of light and dark bands. Today those bands are known to correspond to regional variations in the amounts of the two nucleotide base pairs: adenine-thymine (A-T) or

T-A) in contrast with amounts of guanine-cytosine (G-C or C-G).

Genetic abnormalities and diseases occur when one of the following events happens: a) one chromosome copy is missing, b) extra copies of a chromosome are present, c) a chromosome breaks and its fragment is fused into another chromosome (insertion), d) a fragment is deleted, e) a gene is transferred from one chromosome to another (translocation), f) duplication of a chromosomal segment occurs, or g) inversion of a chromosomal segment occurs. Down syndrome, for instance, is caused by the presence of a third copy of chromosome 21.

In nondividing cells, it is not possible to distinguish morphological details of individual chromosomes, because they remain elongated and entangled to each other. However, when a cell is dividing, i.e., undergoing mitosis, chromosomes become highly condensed and each individual chromosome occupies a well-defined spatial location.

Mitotic chromosomes present a constricted region, to which the spindle fibers attach during cellular division. Such a constricted region, known as the centromere or primary constriction, may be located in three different positions in chromosomes. Centromeric position allows the classification of chromosomes in three groups: a) acrocentric: centromere lies very near one end; b) metacentric: centromere at the middle, dividing the chromosome in two equal parts or arms; and c) submetacentric: centromere near the middle, but dividing the chromosome in two unequal arms.

When a chromosome loses its centromere, it is known as acentric. As the centromere is essential for both division and retention of chromosome copies in the new cells, acentric chromosomes will not pass to the daughter cells during the parental cell division. Therefore, daughter cells will lack one chromosome in their karyotype. A karyotype map shows mitotic chromosomes in the mitotic phase, known as metaphase. In metaphase, chromosomes align in pairs. In a normal human karyotype, there are 22 pairs of autosomal chromosomes and two sex chromosomes (X and Y). Each pair of autosomal chromosomes contains two complementary or homologous chromosomes, a maternal and a paternal copy.

Some chromosomes also present a secondary constriction that always appears at the same site. They are also useful, along with centromere position and chromosome size, for identifying and characterizing individual chromosomes in a karyotype.

Karyotype analysis was the first genetic screening utilized by geneticists to assess inherited abnormalities, like additional copies of a chromosome or a missing copy, as well as DNA content and gender of the

individual. With the development of new molecular screening techniques and the growing number of identified individual genes, detection of other more subtle chromosomal mutations is now possible (e.g., determinations of gene mutations, levels of gene expression, etc.). Such data allow scientists to better understand disease causation and to develop new therapies and medicines for those diseases.

Cleft lip and palate

Definition

A cleft is a birth defect that occurs when the tissues of the lip and/or palate of the fetus do not fuse very early in pregnancy. A cleft lip, sometimes referred to as a hare-lip, is an opening in the upper lip that can extend into the base of the nostril. A cleft palate is an opening in the roof of the mouth.

Description

“Cleft” means “split or separated.” During the first months of pregnancy, separate areas of the face, such as bony and muscular parts, the mouth, and the throat, develop individually and then join together. If some parts do not join properly, the result is a cleft, the type and severity of which can vary. During the fifth through ninth weeks of pregnancy, genetic and environmental factors are most likely to affect lip and palate development. Cleft palate occurs when the right and left segments of the palate fail to join properly. The back of the palate (toward the throat) is called the soft palate, and the front section (toward the mouth opening) is known as the hard palate. A cleft palate can range from just an opening at the back of the soft palate, to a nearly complete separation of the roof of the mouth (soft and hard palate). In some cases, an infant with a cleft palate may also have a small lower

This axial (cross-sectional) CT image of a child shows a bony cleft along the anterior maxilla (left). Cleft lip and palate can be easily demonstrated using CT imaging and is a good technique to determine the extent of the malformation prior to surgery. (Living Art Enterprises/Science Source)

jaw and have difficulty breathing. This condition is called Pierre Robin sequence.

Infants born with cleft lips will have an opening involving the upper lip. The length of the opening ranges from a small notch to a cleft that extends into the base of the nostril. Cleft lips may involve one or both sides of the lip. They occur when the lip elements fail to come together during fetal development, thus creating an opening in the upper lip between the mouth and nose. The lip looks split. The incomplete cleft lip results in less facial distortion because the connected parts of muscle and tissue have a stabilizing effect. In a complete cleft lip, the muscles pull away from the center of the face, resulting in distortion of the nose and mouth. A cleft on one side is called a unilateral cleft. If a cleft occurs on both sides, it is called a bilateral cleft.

Cleft lips can develop with or without cleft palates, which may also occur without cleft lips.

Genetic profile

The causes of clefts are still poorly understood. Although it is not completely clear what causes cleft deformities, there is a definite genetic (inheritable) component. Most scientists believe that clefting occurs as a result of a combination of genetic and environmental

factors. In the United States and western Europe, researchers report that a family history of facial clefts is present in approximately 40% of all cases. The likelihood of a baby being born with a facial cleft increases if a first-degree relative (mother, father, or sibling) has a cleft. Mothers who abuse alcohol and drugs, lack vitamins (especially folic acid) during the first weeks of pregnancy, or have diabetes are more likely to have a child with facial clefts. Clefts may occur alone or with other abnormalities that may be hidden or obvious. Up to 13% of infants with a cleft lip or palate have other birth defects. Some cases involve genetic syndromes that may result in specific problems for the infant and may have a high risk of affecting others in the family. For that reason, newborns with clefts should be thoroughly examined by a specialized physician soon after birth.

Demographics

In the United States, about one in every 1,600 babies is born with cleft lip with cleft palate, about one in every 2,800 babies is born with cleft lip without cleft palate, and about one in every 1,700 babies is born with cleft palate. Boys are twice as likely as girls to have cleft lip with or without cleft palate. Girls are more likely than boys to have cleft palate without cleft lip. In cleft lip with cleft palate, the sex ratio correlates with the severity and laterality of the cleft. Clefts may affect the left or right side of the mouth only (unilateral) or both sides (bilateral). The prevalence of clefts varies considerably in different racial groups. In whites, cleft lip and cleft lip with cleft palate occur significantly more often in males, and cleft palate occurs significantly more often in females. The lowest prevalence rate is for blacks. Cleft lip and cleft palate are more common in families who are Asian, Hispanic, or Native American. A high prevalence of cleft lip is seen in the Japanese population, however, and the highest prevalence is noted in the North American Indian populations. In contrast, no remarkable variation among races was found in isolated cleft palate.

Risk factors

Several factors may increase the risk of cleft lip and cleft palate. Parents with a family history of cleft lip or cleft palate have a higher risk of having a baby with a cleft lip or cleft palate. Women who binge-drink during the first weeks of pregnancy are more likely than other women to have a baby with a cleft lip or cleft palate. Not getting enough nutrients, like folic acid, before and during pregnancy is also a risk factor. Other risk factors include having diabetes before pregnancy, being obese during pregnancy, having certain infections, and taking certain medicines during pregnancy.

Illustration of a baby with a cleft palate. A cleft palate is a deformity resulting in an opening in the upper lip when the facial structures do not fuse properly. (Gwen Shockey/ Science Source)

Signs and symptoms

Babies born with a cleft lip will have an elongated opening in the upper lip. The size of this opening may range from a small notch to an opening that extends into the base of the nostril. The cleft lip may be below the right or left nostril or below both nostrils.

Babies born with a cleft palate will have an opening in the roof of the mouth. The size and position of the cleft varies, and it may involve only the hard palate or only the soft palate and may occur on both sides of the center of the palate.

In some cases, the cleft palate will be covered with the normal lining of the mouth and can only be felt by the examiner.

Infants with cleft lips and palates have feeding difficulties, which are more severe in those with cleft palates. The difficulty in feeding is due to the baby's being unable to achieve complete suction. In the case of a cleft in the hard palate, liquids enter the nose from the mouth through the opening in the hard palate.

A cleft palate also affects a child's speech, since the palate is necessary for speech formation. The child's speech pattern may still be affected despite surgical repair.

Ear infections are more common in babies born with cleft palates. The infections occur because the muscles of the palate do not open the Eustachian tubes, which drain the middle ear. This allows fluid to collect and increases the risk of infection and hearing loss.

Teeth may also erupt misaligned.

Diagnosis

Cleft lip and palate can be diagnosed before birth by ultrasound. After birth, they are diagnosed by physical exam.

Treatment and management

Traditional

If cleft lip and/or palate are diagnosed by ultrasound before birth, further testing may be necessary to diagnose associated abnormalities if present. Referral to a cleft team is essential. A cleft team consists of specialists in the management of patients with clefts and includes surgeons as well as nurses and speech therapists. Members of the team inform the parents of all aspects of management. Feeding methods are also discussed, since feeding is the first problem that must be addressed. It may be possible to breast-feed a baby born with only a cleft lip, but babies born with cleft palates usually have more problems with feeding and frequently require special bottles and teats. A palatal obturator is a device that fits into the roof of the mouth, thus blocking the cleft opening and allowing easier suckling.

Surgery to repair cleft lips is sometimes performed after orthodontic treatment to narrow the gap in the upper lip. Orthodontic treatment can involve acrylic splints with or without screws, or the use of adhesive tape placed across the gap in the lip. The orthodontic treatment for cleft lip should begin within the first three weeks of life and continue until the cleft lip is repaired.

The timing of surgical cleft lip repair depends on the judgment of the surgeon who will perform the operation. The procedure is usually performed between one and three months of age. The goals of the operation are to close the gap in the upper lip, place scars in the natural skin curves, and repair muscle so that the lip appears normal during movement. The closure is done in the three layers (skin, muscle, and mucosa) that line the inside of the lip. At the time of the procedure, if the nose is shaped abnormally because of the cleft lip, it is also corrected.

Sometimes further surgery may be needed on the lip and/or nose to refine the result.

The goals of the surgeon repairing a cleft palate are normal speech, normal facial growth, and hearing for the affected infant. The repair of the cleft palate is usually performed between three and 18 months of age. The timing may extend beyond this and varies with the type of cleft plate and the center where the procedure is being performed. Depending on the type of cleft palate, more than one operation may be needed to close the cleft and improve speech.

Babies born with cleft palates are vulnerable to ear infections. Their Eustachian tubes do not effectively drain fluid from the middle ear, so fluid accumulates and infection sets in, which may lead to hearing loss. These children require drainage tubes to be inserted in order to prevent fluid accumulation.

Babies born with clefts usually require orthodontic treatment between ages 13 and 18. They also require speech therapy.

Alternative

Nonsurgical treatment of a cleft palate is available for patients who are at high risk for surgery and consists of a prosthetic appliance worn to block the opening in the palate.

Nutritional concerns

Infants with cleft lip or cleft soft palate generally have few feeding problems. However, when the cleft involves the hard palate, the infant is usually not able to suck efficiently. For those infants, caregivers must experiment with various feeding techniques, such as special nipples or alternate feeding positions. The infant with a cleft should be held in a nearly sitting position during feeding to prevent the breast or formula milk from flowing back into the nose. They should be burped frequently, approximately every three or four minutes. The sucking reflex is strong in all infants and should be encouraged in infants with facial clefts even if the sucking is inefficient, since the reflex seems to help the later development of speech. It is important to keep the cleft clean and not to allow formula, mucus, or other matter to collect in it.

Prevention

While little is known about how to prevent clefts, researchers from the California Birth Defects Monitoring Program found that women who are considering pregnancy may be able to reduce the risk of facial clefts (and possibly other birth defects) in their offspring by taking a multivitamin containing folic acid for one month prior to becoming pregnant. Other studies have shown that fetuses

QUESTIONS TO ASK YOUR DOCTOR

- Can the cleft be surgically corrected?
- What are the treatment options?
- Is child development affected by clefting?
- At what age should surgery be performed?

with certain predisposing genes may be at increased risk for cleft palate if their mothers smoke. Because some types of medications (for example, some drugs used to treat epilepsy) have been linked to increased risk of clefts, women who take medications for chronic illnesses should check with their doctors before they become pregnant.

Prognosis

Individuals born with cleft lip and palate have a good prognosis, and approximately 80% will develop normal speech. There is no known means of preventing clefting. Good prenatal care is essential, and avoiding harmful substances appears to reduce the risk.

Cleidocranial dysostosis see **Cleidocranial dysplasia**

Cleidocranial dysplasia

Definition

Cleidocranial dysplasia (CCD), also known as cleidocranial dysostosis, is a hereditary condition that causes abnormal formation of the collarbone, delayed fusion of the bones in the skull, extra teeth to appear, short stature, and other changes in the skeleton.

Description

Cleidocranial dysplasia is one of the skeletal dysplasia conditions, a large family of disorders involving abnormal growth and development of the skeleton.

CCD involves a characteristic group of abnormalities that affect mostly the skull, teeth, and clavicles. Other bones, such as the ribs, pelvis, and bones of the hands

KEY TERMS

Autosomal dominant—Requiring only one copy of the mutated gene to cause the disorder.

Clavicle—Also called the collarbone. Bone that connects the shoulder and the breast bone.

Complete penetrance—Condition in which all who carry the gene display some symptoms.

Deciduous teeth—The first set of teeth or “baby teeth.”

Fontanelle—One of several soft spots on the skull where the developing bones of the skull have yet to fuse.

Hypoplasia—Incomplete or underdeveloped tissue or organ.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual and can be transmitted to offspring. The change may manifest as disease.

and feet may also be affected. Older children and adults with CCD are typically shorter than average. Most individuals with this condition do not have significant physical or mental disability.

Genetic profile

CCD is an autosomal dominant condition. This means that it only takes one copy of the mutated gene to cause the disorder. The symptoms can vary, but the disorder has complete penetrance, which means that all individuals who carry the gene for CCD have some symptoms. It is estimated that one-third of cases represent *de novo*, or new, mutations. The gene responsible for CCD has been mapped to the short arm of chromosome 6 and is called *RUNX2*. There are other names for the gene, including *CBFA1*. This gene provides instructions for making a protein that is involved in making and maintaining bone and cartilage. More than 70 mutations in the *RUNX2* gene have been identified in people with CCD, and the *RUNX2* gene causes most cases of the condition.

Demographics

CCD is rare, and occurs in only about one per million people around the world. More than 500 cases of CCD among individuals of various ethnic backgrounds have been described in the medical literature. The incidence of CCD is reported to be highest around Cape Town, South Africa. Research on this population helped localize the gene responsible for the condition.

Signs and symptoms

Infants with CCD typically show a delay or failure of the fusion of the openings between the bones of the skull. In some cases, the anterior fontanelle (the soft spot on an infant's head) or other areas of the skull may remain unfused through life. A typical facial appearance in people who have CCD includes a broad forehead and widely spaced eyes. The overall head size is usually at the upper limit of normal.

Almost every person with CCD has some degree of hypoplasia, which means underdevelopment, of the collarbones. In severe cases, both clavicles may be absent. Most often, the child has hypoplasia of the outside ends of the collarbones. Depending on how severely underdeveloped the collarbones are, the child's shoulders may appear abnormal. Some people with CCD appear to have narrow, sloping shoulders. Some have the unusual ability to bring their shoulders together beneath their chin. This hypoplasia of the collarbones usually does not result in physical disability for the individual.

Dental abnormalities are common among people with CCD and are considered characteristic of the disorder. Almost all individuals are slow to lose their deciduous teeth (baby teeth), and have delayed eruption of the permanent teeth. Some people with CCD describe "living without teeth" until their permanent teeth started growing. Additionally, the person may have a large number of extra teeth. These extra teeth can be so numerous that they constitute nearly a third complete set of teeth. Additionally, the enamel of the teeth may be abnormal and prone to decay.

Other signs of CCD include a small rib cage with short or abnormal ribs. The vertebrae of the spine may be malformed. The pelvis may be underdeveloped with an increased space between the pubic bones. The growth of the bones in the hands and feet is often abnormal; most are shorter but others are longer than normal. Final height in adults with CCD is usually shorter than expected given the family background.

More unusual complications associated with CCD include scoliosis (curvature of the spine), bone fragility, deafness, cleft palate, and a small jaw.

Diagnosis

The diagnosis of CCD is typically made by the doctor following review of the information obtained from physical exams, case history, or x-rays. The underdeveloped collarbone may only be seen through x-rays.

The combination of hypoplastic clavicles, open fontanelles, and extra teeth is considered typical of CCD. The multiple dental problems in CCD are also quite

QUESTIONS TO ASK YOUR DOCTOR

- What are the primary signs and symptoms of cleidocranial dysplasia?
- How is this disorder transmitted from one generation to the next?
- What types of treatment should be considered first for a child diagnosed with cleidocranial dysplasia?
- Will a child born with cleidocranial dysplasia develop physical and mental problems other than its primary symptoms?

specific and the diagnosis is evident in any individual with normal deciduous teeth, delayed eruption of permanent teeth, and multiple extra teeth.

Testing for *RUNX2* gene mutations may also be performed. Identification of a mutation may confirm the initial diagnosis or allow diagnosis before birth.

In a few cases, recognition of the features of CCD by ultrasound imaging, a technique that produces pictures of the fetus, has led to diagnosis of the condition before birth.

Treatment and management

There is no specific treatment for cleidocranial dysplasia. Typically, a course of treatment is designed to manage the specific symptoms.

Children with CCD may be screened for deafness.

Long-term dental treatment is often required. Surgery may be performed to remove the baby teeth and open the bony coverings surrounding the permanent teeth, with the goal of promoting their eruption. Orthodontic procedures may be required to align the teeth.

A pregnant woman with CCD may have to deliver her child by caesarean section because of her pelvic abnormality.

Prognosis

CCD is not expected to affect life expectancy in most cases, and most people with the disorder enjoy good overall health.

In some newborns, the small rib cage and reduced lung capacity may lead to respiratory distress. Height is often lower compared to that of other family members. The clavicular hypoplasia does not appear to significantly

impair function. Some individuals with hypoplastic or absent collarbones have worked in physically demanding jobs without difficulty. Dental problems are expected and are sometimes severe enough to cause dental disability. Intelligence is usually normal.

Clubfoot

Definition

Clubfoot is a condition in which one or both feet are twisted into an abnormal position at birth. The condition is also known as talipes.

Description

True clubfoot is characterized by abnormal bone formation in the foot. There are four variations of clubfoot, including talipes varus, talipes valgus, talipes equinus,

An untreated clubbed foot. (Mike Devlin/Science Source)

and talipes calcaneus. In talipes varus, the most common form of clubfoot, the foot generally turns inward so that the leg and foot look somewhat like the letter J. In talipes valgus, the foot rotates outward like the letter L. In talipes equinus, the foot points downward, similar to that of a toe dancer. In talipes calcaneus, the foot points upward, with the heel pointing down.

Clubfoot can affect one foot or both. Sometimes an infant's feet appear abnormal at birth because of the intra-uterine position of the fetus birth. If there is no anatomic abnormality of the bone, this is not true clubfoot, and the problem can usually be corrected by applying special braces or casts to straighten the foot.

True clubfoot is usually obvious at birth because a clubfoot has a typical appearance of pointing downward and being twisted inward. Since the condition starts in the first trimester of pregnancy, the abnormality is quite well established at birth, and the foot is often very rigid. Uncorrected clubfoot in an adult causes only part of the foot, usually the outer edge or the heel or the toes, to touch the ground. For a person with clubfoot, walking becomes difficult or impossible.

Risk factors

Risk factors for clubfoot include smoking and a family history of clubfoot or neuromuscular disorders, such as cerebral palsy or spina bifida.

Genetic profile

Experts do not agree on the precise cause of clubfoot. Genetic patterns of inheritance have been extensively investigated using family studies and other epidemiological methods. No definitive conclusions have been reached, although a Mendelian pattern of inheritance is suspected. This may be due to the interaction of several different inheritance patterns, different patterns of

development appearing as the same condition, or a complex interaction between genetic and environmental factors. A 2009 study reported that two biologically plausible candidate genes are present on chromosomes 3 and 13, a result that supports the continued search for responsible genes. Clubfoot can also be present in people with such syndromes as Ehlers-Danlos or Loeys-Dietz.

A family history of clubfoot has been reported in 24.4% of families in a single study. These findings suggest the potential role of one or more genes being responsible for clubfoot.

Several environmental causes have been proposed for clubfoot. Obstetricians think that intrauterine crowding causes clubfoot. This theory is supported by a significantly higher incidence of clubfoot among twins compared to singleton births. Intrauterine exposure to the drug misoprostol has been linked with clubfoot. Misoprostol is commonly used when trying, usually unsuccessfully, to induce abortion in Brazil and in other countries in South and Central America. Researchers in Norway have reported that males who are in the printing trades have significantly more offspring with clubfoot than men in other occupations. For unknown reasons, amniocentesis, a prenatal test, has also been associated with clubfoot. The infants of mothers who smoke during pregnancy have a greater chance of being born with clubfoot than offspring of women who do not smoke.

Demographics

The ratio of males to females with clubfoot is 2.5 to 1. The incidence of clubfoot varies only slightly. In the United States, the incidence is approximately 1 to 4 in every 1,000 live births. A 1980 Danish study reported an overall incidence of 1.2 in every 1,000 children; by 1994, that number had doubled to 2.41 in every 1,000 live births. A reason for the increase has yet to be identified.

Signs and symptoms

The physical appearance of a clubfoot may vary. However, at birth, an affected foot usually turns inward and points downward. It resists realignment. The calf muscle may be smaller and less well developed than normal. One or both feet may be affected.

Diagnosis

Examination

True clubfoot is usually recognizable and obvious on physical examination. Clubfoot is diagnosed by physician inspection. This is most often completed immediately after birth.

QUESTIONS TO ASK YOUR DOCTOR

- How does clubfoot affect a child?
- Can it be corrected by nonsurgical treatment?
- What are the outcomes?
- What are the surgical options?
- How do various types of clubfoot differ from each other?
- What kinds of treatment are available for a child born with a clubfoot?
- At what age should those treatments begin, and what side effects may be associated with the treatments?
- To what extent will a child born with clubfoot be able to live a normal life after treatment?

Tests

A routine x-ray of the foot that shows the bones to be malformed or misaligned supplies a confirmed diagnosis of clubfoot. Ultrasonography is not always useful in diagnosing the presence of clubfoot prior to the birth of a child.

Treatment and management

Traditional

Most orthopedic surgeons agree that the initial treatment of congenital (present at birth) clubfoot should be nonoperative. Nonsurgical treatment should begin in the first days of life to take advantage of the favorable fibro-elastic properties of the foot's connective tissues, those forming the ligaments, joint capsules, and tendons. The Ponseti method of stretching and casting has been used with increasing success since the 1990s. The Ponseti method requires that a doctor stretch the child's affected foot toward its anatomically correct position and hold it in place with a cast. The foot is realigned and a new cast applied weekly for several weeks. Once the correct position has been achieved, a brace must be worn during periods of sleep to maintain the correction. To be successful, the method requires active parental involvement. Because the cause of clubfoot is unknown, there are no measures to specifically prevent it. However, pregnant women can take steps to limit the risk of birth defects such as clubfoot by avoiding smoking, alcohol consumption, or the intake of medications not approved by a physician.

Surgical

When clubfoot is severe enough to require surgery, the condition is usually not completely correctable, although significant improvement is possible. In the most severe cases, surgery may be required, especially when the Achilles tendon, which joins the muscles in the calf to the bone of the heel, needs to be lengthened. Because an early operation induces fibrosis, a scarring and stiffness of the tissue, surgery should be delayed until an affected child is at least three months old.

Much of a clubfoot abnormality can be corrected by the use of manipulation and casting during the first three months of life. Proper manipulative techniques must be followed by applications of appropriately molded plaster casts to provide effective and safe correction of most varieties of clubfoot. Long-term care by an orthopedist is required after initial treatment to ensure that the correction of the abnormality is maintained. Exercises, corrective shoes, or nighttime splints may be needed until the child stops growing.

Prognosis

With prompt, expert treatment, clubfoot is usually correctable. Most individuals are able to wear regular shoes and lead active lives. If clubfoot is not appropriately treated, the abnormality becomes fixed. This has an effect on the growth of the leg and foot, and some degree of permanent disability usually results.

Cobblestone dysplasia see **Lissencephaly syndrome**

Cockayne syndrome

Definition

Cockayne syndrome (CS) is a rare inherited disorder that results in an extreme sensitivity to ultraviolet (UV) irradiation, dwarfism, intellectual deficits, and premature aging.

Description

Since first reported in 1936 by Dr. Edward A. Cockayne, fewer than 200 cases of this disorder have been documented in medical literature. At birth, newborns with CS may have microcephaly (small-sized head) and low birth weight. During the first year of life, they do not feed well, and as a result they suffer from growth failure and delayed development. The disease usually results in death during the teenage years.

Cockayne syndrome can be divided into subtypes, which are distinguished by the severity and age of onset of symptoms. Classical or Type I CS is characterized by symptoms that appear in early childhood. Type II CS has severe symptoms that are apparent at birth. It is also called cerebro-oculo-facio-skeletal (COFS) syndrome or Pena-Shokeir syndrome Type II. A few cases of Type III CS have been diagnosed with the onset of symptoms in late childhood. There are also cases that combine features of CS and another photosensitivity disorder called xeroderma pigmentosum.

Risk factors

People with a family history of CS are at risk, since defective genes are associated with the disease.

Demographics

CS occurs in fewer than one in 250,000 births and does not affect any single ethnic group more than any other. Males and females are equally affected.

Signs and symptoms

CS results from mutations in the *ERCC6* and *ERCC8* genes (also known as the *CS* genes) located on chromosomes 10 and 5, respectively. An affected person has inherited one abnormal or nonworking gene from each parent, a pattern that is consistent with autosomal recessive inheritance. When functioning normally, the *CS* genes help cells remove and destroy deoxyribonucleic acid (DNA) errors from strands undergoing active transcription. The *CS* genes also allow cells to synthesize ribonucleic acid (RNA) after exposure to UV light. Although the parents of an affected child may be normal, each of them carries an abnormal gene for CS. Therefore, they have a 25% risk with each pregnancy of having another affected child.

As Cockayne syndrome is divided into four subtypes, symptoms vary but can be very striking. The symptoms associated with each subtype overlap. The most severe end of the spectrum is Type II CS in which individuals show a prenatal onset of symptoms. Classical or Type I CS is characterized by symptoms that appear in early childhood and are more severe than those seen in Type III. Individuals with XP-CS have mutations in *ERCC6* and, similar to XP, have facial freckling and early skin cancers. These individuals also have some of the less threatening features of CS.

The spectrum of symptoms associated with CS includes developmental delay, failure to grow during the first year of life, a small head size, dental anomalies, and progressive hearing loss. Intellectual impairment in the mild-to-moderate range is found in all patients with CS. A small number of patients will have severe-to-profound intellectual deficits, with some having only a few words of speech. Skin rashes appear with exposure to sunlight, and patients develop dry, scaly skin and thin hair. As part of the disease process, the skin develops an aged, leathery appearance. Although the eyes appear normal early in life, the retina later loses its pigment or color and develops a “salt-and-pepper” appearance. If cataracts appear within the first three years of life, the patient usually has the more severe form of CS that leads to death before adolescence. More than half of patients with CS have sensorineural hearing loss. The range of loss is from mild to severe.

Another finding of CS is an unusual gait (pattern of walking), caused by a combination of leg spasticity and contractures of the hips, knees, and ankles. The stooped posture, often seen in CS, results from kyphosis and joint

contractures. Some of the first signs of neurological changes are increased or decreased muscle tone and reflexes.

The most notable sign of CS is precocious senility (premature memory loss and confusion). Patients experiencing precocious senility undergo neurological changes that resemble normal aging. The central and peripheral nervous systems lose myelin, and neurons disappear from the central cortex and cerebellum. However, unlike in normal aging, these changes occur at an extremely accelerated pace, leading to death during early adolescence.

Diagnosis

The diagnosis of Cockayne Syndrome is often difficult to establish, depending on the type of CS, since many of the symptoms develop gradually. A diagnosis is generally made based on the observation of any combination of the characteristic symptoms during a medical examination. Genetic testing for mutations in the *ERCC6* and *ERCC8* genes or a DNA repair assay on fibroblasts can confirm the diagnosis. The fibroblasts of a person with CS present notably decreased development.

Treatment and management

There is no cure for CS at present. Patients are treated according to the symptoms they have. Physical therapy helps to prevent joint contractures that limit walking. Poor feeders may require a gastrostomy tube to prevent malnutrition. Patients are also advised to use sunscreen liberally and to limit their exposure to sunlight. Special-needs education helps to maximize the child’s learning potential.

Since carriers of the gene that causes CS appear normal, and routine testing before pregnancy is not yet available, couples will not be aware of their risk until they have an affected child. For future pregnancies, prenatal diagnosis can determine whether the baby has CS.

Prognosis

Scientists have determined that some of the symptoms of CS are caused by defects in the chemical pathway that repairs DNA. One of these defects leads to damage in mitochondria, which are organelles in the cell involved in respiration and energy production. The damage allows the buildup of a protein called HTRA3 that appears to interfere with mitochondrial function. By using an antioxidant, scientists have been able to decrease HTRA3 to normal levels and prevent mitochondrial damage in cells of some types of CS in the laboratory. This work is still in the experimental stage, and as of 2021 it does not have therapeutic applications for individuals, but it is a step toward understanding the chemical pathway that causes CS symptoms. At present, the prognosis for CS is grim. Most patients die during the early adolescent years. Some survive until

QUESTIONS TO ASK YOUR DOCTOR

- What symptoms suggest a diagnosis of Cockayne syndrome in a newborn child or infant?
- What kind of genetic testing is currently available?
- What is the risk of CS for future pregnancies?
- What are the major health issues associated with CS?
- What confirmatory tests are available for such a diagnosis?
- What are the treatment options for Cockayne syndrome?
- Are there treatments available that will slow the progress of this disorder?
- What is the long-term prognosis for a child born with Cockayne syndrome?

early adulthood. However, some patients have a more severe form and may die during early childhood.

Clinical trials for Cockayne syndrome are underway; there are 7 as of 2021. Participation in a U.S. clinical trial is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>.

CODAS syndrome

Definition

CODAS syndrome is a very rare genetic disorder that affects five major body organs or systems: the brain, eyes, ears, teeth, and skeleton. The acronym CODAS stands for cerebral, ocular, dental, auricular, and skeletal. CODAS syndrome was named by the team of Canadian researchers who identified it in 1991 in a single patient from Manitoba.

Description

Children with CODAS syndrome have a distinctive set of abnormalities that include developmental delays, cataracts in both eyes, deformities of the facial features, misshapen ears combined with mild to moderate hearing loss, abnormally shaped teeth combined with delayed eruption of baby teeth, delayed maturation of the skeleton together with hip displacement and scoliosis, and overall short stature.

Genetic profile

The gene whose mutations are responsible for CODAS syndrome was not identified until early 2015. Two groups of geneticists, one in southeastern Pennsylvania and the other in Switzerland, identified the specific gene as the

KEY TERMS

Auricular—Pertaining to the ear.

Autosomal recessive—A pattern of inheritance in which two copies of a defective gene on a nonsex chromosome must be present for a disease or inherited trait to develop in an individual.

Autosome—Any human chromosome other than a sex chromosome.

Corpus callosum—A wide, flat bundle of nerve fibers that connects the two cerebral hemispheres and allows communication of nerve impulses between the two hemispheres.

Cryptorchidism—The absence of one or both testes in the male scrotum at the time of birth.

Epicanthal fold—A skinfold in the upper eyelid that covers the inner angle of the eye. Epicanthal folds are common in persons of Asian, Native American, Alaska Native, or Berber heritage, but they may also occur as a symptom of some genetic syndromes.

Fistula (plural, fistulae)—An abnormal connection between two hollow body organs or spaces.

Hypotonia—A state of low muscle tone that often involves loss of muscle strength as well.

Mitochondria (singular, mitochondrion)—An organelle found in most human cells that generates most of the cell's supply of adenosine triphosphate (ATP), a critical source of chemical energy. Mitochondria are sometimes described as the powerhouses of the cell.

Omphalocele—A birth defect in which the infant's intestines, liver, and occasionally other organs remain outside the abdomen in a sac. Omphaloceles result from the failure of the abdominal muscles to develop properly.

Organelle—A specialized subunit within a cell.

Peptidase—Any enzyme that breaks down proteins. The gene whose mutations cause CODAS syndrome codes for a peptidase enzyme. Peptidases are also called proteases.

Ptois—Drooping or falling of the upper or lower eyelid.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than 10 degrees to the right or left as the doctor faces the patient.

LONPI gene on chromosome 19 at 19p13.2. This gene encodes an enzyme called lon peptidase 1, which helps to remove damaged proteins from the mitochondria of cells and thus maintain quality control of the proteins produced in the cell. Lon peptidase 1 is also thought to play a role in regulating gene expression. Although mutations in the *LONPI* gene have been identified as the cause of CODAS syndrome, it is not yet clear how these mutations cause the specific signs and symptoms of the syndrome.

CODAS syndrome is inherited in an autosomal recessive pattern, which means that two copies of the mutated *LONPI* gene, one from each parent, are required for the symptoms of the syndrome to appear.

Demographics

CODAS syndrome affects fewer than one person per million. As of 2010, only four cases had been reported worldwide, one each in France, Brazil, and western Canada, in addition to the original patient in Canada. The geneticists in Pennsylvania discussed their findings of four different *LONPI* mutations in ten patients, who included the two Canadian children identified by 2010, as well as eight Amish children from six different Old Order Amish families in southeastern Pennsylvania. The total number

of children identified as having the syndrome between 1991 and 2015 was only 12, which suggests that CODAS syndrome is extremely rare. In 2019, two Korean siblings were diagnosed with CODAS syndrome, bringing the total number of cases to 14 as of 2021.

Although 9 of these 14 patients are of Amish/Swiss or German/Mennonite heritage, the Korean siblings are of full Korean heritage, the Brazilian patient is of Portuguese ancestry, the French patient's parents immigrated from Morocco, and the remaining Canadian patient is of mixed European ancestry. Therefore, it is difficult to determine whether the syndrome may occur in people of other racial or ethnic groups. It is known, however, that males and females are equally affected.

Signs and symptoms

The signs and symptoms of CODAS syndrome are as follows, grouped according to the organ or body system involved:

- **Cerebral:** Delayed motor development, cognitive impairments, and underdevelopment of the corpus callosum, a band of nerve fibers in the brain that connects the two cerebral hemispheres.

- Ocular: Congenital cataracts, epicanthal folds, drooping eyelids (ptosis), and cross-eyes.
- Facial: Abnormal facial features include a grooved or abnormally short nose, an overly broad forehead, and a flattened midface.
- Dental/oral: Delayed eruption of baby teeth, abnormally shaped teeth with protrusions from the enamel, excessive salivation, and difficulty swallowing. Some patients also lack vocal cords.
- Auricular: Ears that are folded, crumpled, or flattened against the skull, and hearing loss that appears after the first few months of life.
- Skeletal: Short stature, abnormally shaped spinal vertebrae, scoliosis, hip displacement, delayed ossification of the long bones in the legs, hypotonia, excessive mobility in the joints, abnormally short finger bones, and development of knock knees or feet turned too far outward in later childhood.

Other symptoms found in some (though not all) children with CODAS syndrome include cryptorchidism (undescended testicles) in male infants, an abnormal passage (fistula) between the rectum and vagina in female infants, seizures, heart defects, structural abnormalities in the urinary tract, an abnormal opening in the abdominal wall that allows the liver and intestines to protrude (omphalocele), and an imperforate (closed) anus.

Diagnosis

In the early cases, the diagnosis of CODAS syndrome was made after the child's birth on the basis of the child's clinical features. Single-gene testing for mutations in the *LONP1* gene has been available since 2018.

Treatment and management

Treatment of patients with CODAS syndrome is essentially supportive, as many patients do not survive early infancy. Some of the skeletal abnormalities may be corrected by surgery in selected patients.

Families of Old Order Amish or Mennonite heritage who are concerned about the possibility of CODAS syndrome occurring in their children can consult the Windows of Hope Project in Ohio or the Clinic for Special Children in Pennsylvania. These organizations specialize in genetic counseling and testing for families from these faith communities. In fact, two of the geneticists who contributed to the study that was published in January 2015 were staff members of the Clinic for Special Children.

Prognosis

The prognosis of patients with CODAS syndrome is poor. Generalizations are difficult, however, because so few patients with the syndrome have been identified. Some

QUESTIONS TO ASK YOUR DOCTOR

- Have you ever referred a family to the Clinic for Special Children or another genetic counseling service?
- Do you think that the discovery of the association of a specific gene with CODAS syndrome will lead to identification of more cases of the syndrome?
- Do you think that researchers may eventually develop a cure for CODAS and other very rare genetic syndromes?

infants with the syndrome die shortly after birth due to obstruction of the airway, while others are stillborn. Some of the Pennsylvania patients required tube feeding in order to survive the first few days of life. One patient lived to the age of 14 but was killed in an accident. The Korean siblings have benefited from five years of intensive rehabilitation.

Rebecca J. Frey, PhD

Coffin-Lowry syndrome

Definition

Coffin-Lowry syndrome (CLS) is an inherited syndrome characterized by intellectual disability, slow growth, distinctive facial appearance, large soft hands, loose joints, skeletal changes, and low muscle tone (hypotonia). Full expression of the disorder is seen only in males, although females may have some of the physical features and learning disability.

Description

Coffin-Lowry syndrome is one of a large number of intellectual disability syndromes caused by abnormalities (mutations) of genes on the X chromosome. The pattern of physical findings, combined with mental disability,

KEY TERMS

Intellectual disability—Significant impairment in intellectual function and adaptation in society. Usually associated with an intelligence quotient (IQ) below 70.

X-linked—Located on the X chromosome, one of the sex chromosomes. X-linked genes follow a characteristic pattern of inheritance from one generation to the next.

makes the condition readily recognizable, and its frequency makes it one of the most well-known X-linked intellectual disability syndromes. Although CLS was initially considered to be two separate syndromes, Coffin syndrome and Lowry syndrome, the two entities were recognized as the same disease in 1975. Coffin-Lowry syndrome may also be called intellectual disability with osteocartilaginous abnormalities.

Genetic profile

Coffin-Lowry syndrome is caused by mutations in the *RPS6KA3* gene. Located on the short arm of the X chromosome, the *RPS6KA3* gene provides instructions for making a protein that plays an important role in the development and function of the brain and the signal

Coffin-Lowry syndrome: pedigree analysis chart. (Gale)

pathways required for learning, long-term memory, and nerve cell maintenance.

Demographics

Coffin-Lowry syndrome appears to occur in all populations. The full syndrome is seen in males with lesser expression in carrier females. Coffin-Lowry syndrome is estimated to have a prevalence range of 1 in 40,000–50,000.

Signs and symptoms

Although the characteristics of Coffin-Lowry change with age, some manifestations are present from birth. Low muscle tone (hypotonia) and distinctive facial features that include prominent forehead, increased space between the eyes, forward direction of the nostrils, arching of the upper lip, and simple ear structure may be present in infancy. With the passing years, the face elongates, the ears become notably large, the lips and nasal structures thicken, and the mouth is usually open and agape. The hands are large and soft with thick fingers that narrow at their ends. The central part of the chest may bow outward, the spine may curve abnormally (kyphoscoliosis), the knees become flexed, and the feet become flat.

Microcephaly is common, and cardiac abnormalities may be present. Approximately 20% of individuals with Coffin-Lowry syndrome may suffer from episodes of brief collapse with no loss of consciousness called stimulus-induced drop attacks (SIDAs). Triggered by unexpected tactile stimulation, sounds, or excitement, SIDAs typically begin between mid-childhood and the teens.

Growth is slow, as manifest by low birth weight, a small head, and short stature during childhood and adult life. All developmental milestones in infancy and childhood are delayed, and intellectual function is severely impaired.

Female carriers consistently manifest milder characteristics such as short stature, increased space between the eyes, thick nasal tissues, prominent lips, and soft fleshy hands with thick fingers. Intellectual function may be normal or mildly impaired.

Diagnosis

The diagnosis is usually based on the presence of the distinctive facial appearance and intellectual disability. In many cases there will be a family history of other affected males or carrier females. X-rays may show a number of minor features including delayed maturation of the bones, expansion at the ends of the bones of the digits, notching of the bones of the spine, and narrowing of the space between the bones of the spine.

QUESTIONS TO ASK YOUR DOCTOR

- One of my cousins had a child with Coffin-Lowry syndrome. How likely is it that one of my children will be born with the disorder?
- How early is a child with Coffin-Lowry diagnosed with the disease, and what features lead to this diagnosis?
- What kinds of problems will parents of a Coffin-Lowry child have to deal with during his or her lifetime?
- Is a child with Coffin-Lowry syndrome expected to live a normal lifespan? If not, at what age is he or she likely to die?

Molecular genetic testing of *RPS6KA3*, the only gene with mutations known to cause Coffin-Lowry syndrome, can be used to confirm the diagnosis of typical Coffin-Lowry syndrome. This genetic testing cannot, however, be used to rule out the diagnosis because only 25%–40% of individuals with Coffin-Lowry syndrome will have an observable mutation in the *RPS6KA3* gene. Some people with the features of Coffin-Lowry syndrome do not have identified mutations in the *RPS6KA3* gene. In these cases, the cause of the condition is unknown, and diagnosis will be made based on clinical symptoms.

Treatment and management

There is no cure for Coffin-Lowry syndrome, but associated conditions may require treatment. Orthopedic intervention may be required to remediate complications from kyphoscoliosis. Antiepileptic medications may be needed to treat stimulus-induced drop attacks. Because of severe intellectual disability, lifelong supervision is generally required. Developmental progress can be promoted by early intervention, speech therapy, and physical therapy.

Prognosis

Long-term survival is the expectation; however, complications from cardiac anomalies, progressive kyphoscoliosis, and severe intellectual disability may shorten the person's lifespan.

Coffin-Siris syndrome

Definition

Coffin-Siris syndrome is a rare congenital disorder that affects more females than males. Individuals with this syndrome have some degree of intellectual disability or developmental delay, a coarse facial appearance, incompletely formed or absent fifth fingernails, and absent fifth fingers (distal phalanges). Coffin-Siris syndrome is caused by mutations in any of several genes; therefore, the specific symptoms and their severity vary greatly.

Description

Coffin-Siris syndrome was first described in 1970 by Dr. Grange S. Coffin and Dr. Evelyn Siris. It is sometimes known as fifth digit syndrome. All affected children have some degree of intellectual disability or developmental delay and incompletely formed (hypoplastic) or absent fifth fingernails and tips of the fifth fingers (distal phalanges).

KEY TERMS

Consanguinity—A mating between two people who are related to one another by blood.

Hirsutism—The presence of coarse hair on the face, chest, upper back, or abdomen in a female as a result of excessive androgen production.

Hypoplasia—Incomplete or underdevelopment of a tissue or organ.

Hypotonia—Reduced or diminished muscle tone.

Karyotype—A standard arrangement of photographic or computer-generated images of chromosome pairs from a cell in ascending numerical order, from largest to smallest.

Phalanges—Long bones of the fingers and toes, divided by cartilage around the knuckles.

There are some reports of fingers other than the fifth being affected, as well as affected toes and toenails. The face of a child with Coffin-Siris syndrome is usually described as coarse. This includes a flat nasal bridge, broad nose, wide mouth, thick lips, and, in some cases, thick eyebrows, long eyelashes, palate malformations, a large tongue (macroglossia), and a small head (microcephaly). While some infants have an abnormal facial appearance, most of the facial features become more prominent as the child grows. Typically, there is sparse scalp hair in the infant and excessive growth of body hair (hirsutism). Reduced muscle tone (hypotonia), lax joints, delay in bone maturation, and short stature are commonly found. There are reports of frequent upper respiratory and ear infections. Occasionally, children with this disorder have cardiac or spinal abnormalities, hernias, vision or hearing problems, or delayed tooth development (dentition).

Infants with Coffin-Siris syndrome typically have sucking problems and feeding difficulties that may continue as they age. The extent of growth and intellectual disability varies by individual. Intellectual disability is usually reported as moderate. There are delays in motor activities such as rolling over, sitting up, and walking. Speech is usually delayed. Most children are more capable of responding to speech than verbally expressing themselves.

Genetic profile

Coffin-Siris syndrome is caused by mutations in *ARID1A*, *ARID1B*, *SMARCA4*, *SMARCB1*, or *SMARCE1* genes. Each of these genes produces a different portion or subunit of SWI/SNF protein complexes. These protein complexes regulate gene activity by affecting the way DNA and

protein are packaged into chromosomes, a process known as chromatid remodeling. Therefore, SWI/SNF protein complexes affect many different activities, including repairing and copying DNA and controlling the growth, differentiation, and maturation of cells. Thus, defects in any of the proteins in the complexes can have many and varied effects on human growth and development.

Most cases of Coffin-Siris syndrome are sporadic, or random, rather than inherited from a parent. The gene mutations most likely occur during early embryonic development. However, there are some apparently inherited cases of affected siblings and parental relatedness (consanguinity). Coffin-Siris syndrome appears to be an autosomal dominant trait, meaning that one copy of the mutated gene is sufficient to cause the disorder, even in the presence of a second normal gene copy.

Demographics

Coffin-Siris syndrome is very rare, although, as of 2021, 148 cases had been reported in the medical literature. It is more common in females than in males.

Signs and symptoms

At birth, infants with Coffin-Siris syndrome have an absence or incomplete formation of the fifth fingernail and tip of the fifth finger (distal phalanx). Other fingers or toes may also be absent. Infants may have an abnormal facial appearance at birth. As the child grows, the facial abnormalities characteristic of Coffin-Siris syndrome become more apparent. Sparse scalp hair in an infant usually becomes denser with age and excessive hair growth (hirsutism) develops. Infants typically have sucking problems and feeding difficulties that may continue with age.

There is a delay in both gross and fine motor skills. Developments such as sitting up and walking may be delayed or not possible, depending upon the severity of the disorder. Speech is usually delayed, and most children are better able to respond to language than express it. Some older children are able to form short sentences and answer simple questions. Intellectual disability is usually moderate. Social adaptation is usually delayed.

Diagnosis

Diagnosis of Coffin-Siris syndrome may be based upon clinical findings; however, these may overlap with a number of other syndromes. The combination of symptoms such as coarse facial appearance, fifth finger appearance, and developmental delay suggest Coffin-Siris syndrome. X-ray of the hands to reveal the absence of

QUESTIONS TO ASK YOUR DOCTOR

- What characteristic physical and mental features are associated with Coffin-Siris syndrome?
- Is genetic testing available for this disorder, and what information will testing provide?
- What kinds of medications, surgery, and other procedures are available for the treatment of Coffin-Siris syndrome?
- To what extent can a child with Coffin-Siris syndrome be expected to live a normal life during childhood, adolescence, and adulthood?

the fifth finger bone may be the best indicator of this syndrome. Genetic testing can reveal mutations in genes responsible for Coffin-Siris syndrome. Neonatal ultrasounds for cardiac, kidney (renal), and other malformations that may be present with this disorder can also be informative.

Prenatal ultrasound may show intrauterine (occurring within the uterus) growth retardation and reveal the condition of the fifth finger. These symptoms alone cannot conclusively lead to a prenatal diagnosis of Coffin-Siris syndrome, but prenatal genetic testing is possible if the disorder is suspected.

With the identification of gene mutations resulting in Coffin-Siris syndrome, it is expected that diagnostic criteria will become much more precise.

Treatment and management

The treatment or therapy required for children with Coffin-Siris syndrome is based on the particular symptoms of each individual. Some children may require surgery to repair malformations, ranging from cleft palate repair to cardiac, renal, or other surgery. Speech therapy and special education may be required, depending upon the degree of intellectual disability, developmental delay, and motor impairment.

Prognosis

Infants born with Coffin-Siris syndrome may experience a delay or absence of motor and mental abilities, but with appropriate support they can live into adulthood. The prognosis for an individual with Coffin-Siris syndrome depends largely on the degree of intellectual disability and developmental delay.

Cohen syndrome

Definition

Cohen syndrome is a very rare genetic disorder characterized by infantile hypotonia (a weakening of the skeletal muscles), childhood obesity, and several malformations. It is caused by mutations in the *VPS13B* gene, often called the *COH1* gene.

Description

Cohen syndrome was first described in 1973 by Dr. M. M. Cohen, Jr., in three children with distinct physical and developmental characteristics. Since then, several hundred cases have been reported throughout the world, offering a picture of an extremely rare disease with a wide range of clinical characteristics. The initial description given by Cohen included obesity, intellectual disability, poor muscle tone, narrow hands and feet, and distinctive facial features with prominent upper central teeth. Mutations in the *VPS13B* gene are the only known cause of Cohen syndrome. The exact function of this gene is unknown, but it is active (turned on) in most cells of the

body and so is assumed to have an important role in cellular functioning. It may be involved in sorting, transporting, and/or processing proteins within the cell.

Cohen syndrome has also been referred to as Pepper syndrome, Cervenka syndrome, hypotonia-obesity-prominent incisors syndrome, obesity-hypotonia syndrome, and Mirhosseini-Holmes-Walton syndrome.

Genetic profile

The *VPS13B* gene is located on the long arm (q) of chromosome 8 at position 22.2.

Chromosomes are the genetic material passed down from generation to generation. Each chromosome is composed of genes that code for proteins and other regions of DNA that have important functions in the body. A person inherits one copy of each of the 23 chromosomes from the mother's egg, and one copy of each from the father's sperm, so that each cell in the body has two nonidentical copies of each gene.

Cohen syndrome is an autosomal recessive disorder. Recessive means that both copies of the *VPS13B* gene must have a change or mutation for a person to develop Cohen syndrome. An individual with only one mutated *VPS13B* gene will not be affected by the disorder, but each of that person's offspring has a 50% chance of inheriting the mutated gene. These individuals are called carriers. If two carriers have a child together, there is a 25% chance with each pregnancy of having a child affected by the syndrome. At least 73 different mutations in *VPS13B* are known to result in Cohen syndrome. Most of these mutations result in a shortened nonfunctional protein.

Demographics

Fewer than 1,000 cases of Cohen syndrome have been reported worldwide. Due to the extreme rarity of the disease, the exact incidence of Cohen syndrome is not known.

Although Cohen syndrome affects both males and females of all races and genders, different *VPS13B* gene mutations commonly occur in some populations, with different signs and symptoms. Thus, certain clinical findings are family- or ethnicity-specific. For example, Cohen syndrome has been studied extensively in Finland. In the populations studied, individuals diagnosed with the syndrome typically have fewer white blood cells than normal (granulocytopenia), a specific eye abnormality called mottled retina, and intellectual disability. As a rule, they do not have truncal obesity, a common characteristic of Cohen syndrome in other populations. Although the symptoms of Cohen syndrome are known to vary widely between affected individuals within the same family,

affected people within the Finnish populations are very similar to each other in their presentation.

Signs and symptoms

Four main areas are affected by Cohen syndrome: physical appearance, mental function, vision, and hematology (blood function). The list of possible abnormalities and conditions is extensive, however, and each case is different. Even common characteristics of Cohen syndrome are not always present.

Physical appearance

At birth, babies with Cohen syndrome usually appear normal, although they typically have low birth weight. As the babies grow, the various physical signs associated with the syndrome become increasingly obvious.

Narrow hands and feet with long, slender fingers are a hallmark feature, found in approximately 89% of diagnosed individuals. Truncal obesity, or the abnormal deposition of fat around the mid-section of the body, has been observed in roughly 70% of patients. Most individuals with Cohen syndrome have large and rather noticeable front teeth, referred to as prominent upper central incisors. In general, the teeth are abnormal in shape and position. A majority of individuals with Cohen syndrome are also short, with many experiencing growth deficiencies at all stages of life. Microcephaly (a small head) is another common feature of the syndrome.

In addition, there are many other associated physical characteristics that occur less often. The palate (roof of the mouth) may be overly high, arched, and narrow. The mid-face can have an underdeveloped appearance, and the area between the nose and the upper lip (the philtrum) may be very short. The eyes can be down-slanting, and thick hair and eyebrows may be observed.

Mental dysfunction

It is thought that every individual with Cohen syndrome experiences some level of developmental delay. Intellectual disability can range from mild to severe. From infancy, many children are obviously behind in developmental milestones and are not able to sit up or roll over within the same time frame as their peers.

Most children with Cohen syndrome do learn to walk, although there have been a few reported cases of individuals who were wheelchair-bound. There is usually a noticeable delay, with affected children not learning to walk independently until much later than their peers (the normal average age for walking independently is 12 months).

Language deficiencies are also a common occurrence. Many affected individuals never learn to talk or have a vocabulary limited to a few single words and

KEY TERMS

Astigmatism—A cause of poor eyesight, usually due to a refractive error caused by an irregularly shaped cornea.

Autism—A syndrome characterized by a lack of responsiveness to other people or outside stimulus, often in conjunction with a severe impairment of verbal and nonverbal communication skills.

Autosomal—Referring to a chromosome other than the X or Y sex chromosomes.

Coloboma of the iris—A birth defect leading to missing structures within the eye.

Granulocytopenia—A reduced number of white blood cells in the circulation.

Hypotonia—Reduced or diminished muscle tone.

Leucopenia—A decrease in white blood cells.

Microphthalmia—Small or underdeveloped eyes.

Mottled retina—Changes in the retina of the eye causing a loss of visual acuity.

Myopia—Nearsightedness; difficulty seeing objects that are far away.

Neutropenia—A condition in which the number of leukocytes (a type of white or colorless blood cell), especially neutrophils, is abnormally low.

Philtrum—The center part of the face between the nose and lips that is usually depressed.

Retinal dystrophy—Degeneration of the retina, causing a decline in visual clarity.

VPS13B—A gene that is active in most cells of the body; mutations in *VPS13B* are responsible for Cohen syndrome.

two-word phrases. In general, an IQ of less than 50 is considered average for Cohen syndrome.

Visual deficiencies

Vision is affected to varying degrees. Severe limitation in eyesight due to myopia is often observed. Several other dysfunctions and defects of the eyes causing low visual clarity have been reported, including retinal dystrophy, strabismus, astigmatism, microphthalmia, and coloboma of the iris.

Hematologic abnormalities

Cohen syndrome can have a profound effect on the composition of the blood. Abnormally low counts of

white blood cells, referred to as granulocytopenia, were once thought to be a standard symptom. It was hoped that this would assist in early diagnosis because it can be tested for at birth. However, further studies have shown that not all affected individuals suffer from granulocytopenia. Some individuals have no blood disorders associated with their disease at all, while others have various forms of white blood cell problems, such as a reduction in the number of white blood cells (leucopenia) or specialized white blood cells called neutrophils (neutropenia).

Other deficiencies

Hypotonia, or low muscle tone, is found in 90%–100% of persons diagnosed with Cohen syndrome. Babies with hypotonia are described as “floppy” due to their lack of muscle strength. Although the observed hypotonia is not thought to be associated with any nervous system disorder, it does delay the overall development of the child, most notably slowing the development of motor skills.

Social skills

Many studies have described Cohen syndrome patients as being outgoing and friendly with mild hyperactivity and severe attention deficits. There are a few reports of diagnosed individuals showing signs of autism, an extreme form of centering attention and interest on one’s self alone.

Diagnosis

In 1972, Dr. Mirhosseini and others described two patients with symptoms similar to those observed in Cohen syndrome. These patients and a few subsequent cases were given a diagnosis of Mirhosseini-Holmes-Walton syndrome. Over the years, scientific opinion has come to consider Mirhosseini-Holmes-Walton syndrome and Cohen syndrome as different manifestations of the same disease.

Diagnosis of Cohen syndrome is difficult due to the varied nature of the symptoms and a lack of consensus about diagnostic criteria. Most features of Cohen syndrome are not evident in the newborn, and many symptoms, such as truncal obesity and visual deficits, are not easily observed until early childhood. In the past, the average age of diagnosis was approximately 6–8 years. However, as physicians become more aware of the disorder, it is hoped that diagnosis will occur at earlier ages, offering affected individuals the opportunity for early intervention and treatment.

Incorrect diagnosis is not uncommon in patients with Cohen syndrome. Affected individuals may be

QUESTIONS TO ASK YOUR DOCTOR

- How is Cohen syndrome inherited?
- Should family members be screened for *VPS13B* gene mutations?
- Is prenatal screening available for Cohen syndrome?
- How early can Cohen syndrome be diagnosed, and how is the diagnosis made?
- What treatments are available for a child born with Cohen syndrome?

misdiagnosed with Marfan syndrome, Sotos syndrome, hypothyroidism, Prader-Willi syndrome, or intellectual disability of an unknown nature.

A correct and early diagnosis is important to ensure a favorable prognosis for the patient, as well as for genetic screening of the child and family members, and genetic counseling concerning the risks involved in future pregnancies.

Treatment and management

There is no cure for Cohen syndrome. Treatment is focused on improving or alleviating symptoms as they arise.

Early correction of vision problems, usually with glasses, often leads to general improvement in cognitive skills, an area of marked deficit in affected individuals.

As is the case for many disorders involving hypotonia and slowed development, physical and occupational therapies are invaluable tools. These treatment strategies are important at any age, but they should be started as early as possible. There is no need to wait for a definitive diagnosis of Cohen syndrome, since any child with hypotonia can benefit from physical and occupational therapy.

Prognosis

Varying symptoms lead to varying prognoses. Intellectual disability can range from mild to severe. However, there is no way to predict the level of developmental delay a specific child will experience. Language deficiencies also vary a great deal, with some children never learning to speak at all and others speaking in complete sentences. The hypotonia observed in infancy may persist, and moderate obesity usually develops in mid-childhood.

Cole-Carpenter syndrome

Definition

Cole-Carpenter syndrome is a very rare subtype of osteogenesis imperfecta (OI), a group of congenital bone disorders characterized by abnormal bone development (bone dysplasia) resulting from a defective protein in the body's connective tissue. OI is also known as brittle bone disease and fragile bone disease because patients with the disorder are susceptible to frequent bone fractures, as well as various deformities of the skeletal and facial bones. Cole-Carpenter syndrome is distinguished from the more common forms of OI by its genetic profile and by several additional signs and symptoms. It is named for the two American pediatricians who first described it in 1987.

Description

In general, patients with OI suffer from deformities of the long bones; bones that are fragile and easily broken; bluish discoloration of the sclerae (whites of

the eyes); loose joints and poor muscle tone (hypotonia); abnormal curvature of the spine (scoliosis); and a tendency to bruise easily. The severity of these symptoms varies among individuals with the same subtype, as well as between the various recognized subtypes. Some subtypes of OI are characterized by hearing loss in early childhood and failure of the teeth to develop normally.

All forms of OI result from a deficiency of type I collagen. Type I collagen is a protein that forms the long fibers needed for creation of connective tissue in tendons, ligaments, the dermis (the layer of tissue that underlies the skin), and the organic part of bone. Some subtypes of OI are caused by genetic mutations that reduce the quantity of type I collagen produced in the child's body. Other subtypes are caused by mutations that affect the quality of the collagen produced. In Cole-Carpenter syndrome, the child's type I collagen is normal in terms of quality but insufficient in terms of quantity.

The alternate name of Cole-Carpenter syndrome—bone fragility with craniosynostosis, ocular proptosis, hydrocephalus, and distinctive facial features—is derived from the physical characteristics that distinguish the syndrome from other types of OI.

- **Craniosynostosis:** This term refers to an abnormal development of the infant's skull as a result of premature ossification (bone formation) of the fibrous joints between the bones of the skull known as sutures. If these sutures turn to bone shortly after birth, the child's skull may swell on one side of the head or develop another abnormal shape, and the facial features may also be pulled out of their normal alignment by the abnormal growth of the skull.
- **Ocular proptosis:** This term refers to the outward protrusion (bulging) of the patient's eyes.
- **Hydrocephalus:** Hydrocephalus is sometimes referred to as "water on the brain." It results from the accumulation of excess cerebrospinal fluid within the brain. It can cause progressive enlargement of the head in young children, as well as various neurological symptoms.
- **Distinctive facial features:** Children with Cole-Carpenter syndrome have facial deformities that are not found in other types of OI. These deformities include an abnormally small or underdeveloped jaw (micrognathia), an unusually prominent forehead (frontal bossing), and underdevelopment (hypoplasia) of the midface (the area of the face surrounding the nose and cheekbones).

KEY TERMS

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Autosomal recessive—A pattern of inheritance in which two copies of a defective gene on a nonsex chromosome must be present for a disease or inherited trait to develop in an individual.

Autosome—Any human chromosome other than a sex chromosome.

Collagen—The primary structural protein in the connective tissue in the human body.

Cranial suture—Any of the fibrous joints in the skull that hold the bones of the skull together.

Craniosynostosis—A condition in which one or more of the fibrous joints in an infant's skull turns to bone prematurely. As the child's head continues to grow, the growth pattern of the skull is affected, resulting in a misshapen head and often deformed facial features.

De novo mutation—A genetic mutation that is not inherited from either parent.

Dysplasia—A general medical term for an abnormality of development.

Frontal bossing—The medical term for an unusually prominent forehead, often associated with an abnormally heavy brow ridge.

Hydrocephalus—A condition in which there is an abnormally large amount of cerebrospinal fluid in the brain. In young children, the increased pressure resulting from the fluid accumulation may lead to enlargement of the child's head.

Kyphosis—Abnormal outward curvature of the spine resulting in a hunchback.

Micrognathia—The medical term for an undersized or underdeveloped jaw.

Ossification—The process of bone formation.

Proptosis—Bulging of the eye outward from the orbit of the eye. It is also known as exophthalmos.

Sclera (plural, sclerae)—The medical term for the white of the eye.

Scoliosis—Abnormal curvature of the spine, usually defined as greater than 10 degrees to the right or left as the doctor faces the patient.

Wormian bones—Extra pieces of bone that sometimes occur within one or more of the cranial sutures.

Genetic profile

As of 2021, Cole-Carpenter syndrome had been divided into three subtypes. The first two, CLCRP1 and CLCRP2, were identified on the basis of two different genes whose mutations had been identified as causing the syndrome. CLCRP1 is caused by mutations in the *PH4B* gene on chromosome 17 at 17q25.3. This mutation was identified in February 2015. In one of the two original cases described by Cole and Carpenter in 1987, the mutation was inherited from the patient's father; in the other patient, the mutation was *de novo* (new).

CLCRP2 is caused by mutations in a different gene, the *SEC24D* gene on chromosome 4 at 4q26. All three known cases of CLCRP2 involve inherited mutations. The third subtype is caused by a mutation in the cartilage associated protein (CRTAP) [set gene name in italics] gene on the short arm of chromosome 3 at 3p22.3.

The first two subtypes of Cole-Carpenter syndrome are inherited in an autosomal dominant pattern, which

means that only one copy of the defective gene is needed to produce the disorder in the affected child.

Demographics

Cole-Carpenter syndrome is a very rare form of OI. While the more common forms of OI affect about 1 person in every 20,000 to 1 in every 60,000, Cole-Carpenter syndrome is thought to develop in fewer than one person in a million. Only 12 cases had been reported worldwide as of 2021: nine cases of CLCRP1 and three cases of CLCRP2. Males and females appear to be equally affected. As far as is known, all racial and ethnic groups are equally susceptible. The worldwide distribution of Cole-Carpenter syndrome was unknown as of 2021 because the disorder is so rare. Of the 12 known cases, five were reported in Germany, two in the United States, one in China, one in Thailand, one in the United Kingdom, one in Australia, and one in India.

Signs and symptoms

Craniosynostosis, ocular proptosis, hydrocephalus, and distinctive facial features distinguish Cole-Carpenter

syndrome from other forms of OI. Other signs and symptoms of the syndrome are as follows:

- abnormally shaped vertebrae in the spinal column (90% of patients)
- abnormally shaped ribs (90%)
- blue sclerae (90%)
- abnormal vocal quality (90%)
- bowing of the long bones in the arms and legs (90%)
- low bone mineral density (90%)
- delayed eruption of baby teeth (90%)
- short stature (90%)
- kyphosis (50%)
- hypotonia (50%)
- intrauterine growth retardation (50%)
- Wormian bones (50%)

Diagnosis

Diagnosis of Cole-Carpenter syndrome, like other forms of OI, can be made before birth by ultrasound imaging that reveals bone fractures, growth retardation, or deformation of the long bones. Amniocentesis or chorionic villus sampling may be performed to test for the genetic mutations associated with the syndrome.

Diagnosis of the syndrome after birth is based on clinical examination of the infant's physical characteristics together with blood and tissue samples. A tissue sample can be analyzed to determine whether the child's type I collagen is normal. A blood test can be used to detect the presence of the genetic mutations known to cause CLCRP1 and CLCRP2. As of 2021, however, only two laboratories offered molecular genetic testing specifically for Cole-Carpenter syndrome: the Institute of Human Genetics in Germany and Connective Tissue Gene Tests in the United States.

Treatment and management

There is no cure for Cole-Carpenter syndrome or for any other form of OI. Treatment is focused on maintaining the individual's bone strength and preventing new fractures. In general, OI is treated with a combination of braces, physical therapy, and surgery, depending on the severity of each patient's symptoms. Plastic braces and inflatable suits were used as of 2021 to prevent accidental bone fractures, particularly in very young children. Physical therapy is intended to strengthen the individual's weight-bearing bones and joints, improve mobility, and maintain muscle strength. Hydrotherapy—physical therapy in a pool or other body of water—is particularly beneficial because it lowers the risk of fractures during exercise sessions. Surgery may involve the insertion of

QUESTIONS TO ASK YOUR DOCTOR

- Are there any benefits to genetic testing for *de novo* mutations for such rare disorders as Cole-Carpenter syndrome?
- What resources are available to the parents of children with this disorder?
- Can children with Cole-Carpenter syndrome enjoy a reasonably good quality of life?
- Do you think that researchers will discover other genes that cause this disorder?

metal rods in the long bones or procedures to correct malformations of the spinal column.

Medications may be given to patients with OI to treat bone infections (antibiotics in most cases) or to strengthen the bones. Bisphosphonates (a class of drugs that prevent the loss of bone mass) have been tried in some patients with OI to lower the risk of fractures, but the results indicate that these drugs are more helpful in children with OI rather than adults with the condition.

Most patients with OI will eventually need to use such assistive devices as canes, wheelchairs, splints, and grabbing arms to carry out their daily activities. They will also usually need to have their homes or apartments evaluated for the risk of falls or other accidents, and modified with handrails, nonslip rugs, improved lighting, furniture rearrangement, and bathroom redesign.

Prognosis

The prognosis for Cole-Carpenter syndrome is guarded at best. It is significant that two of the 12 cases reported to date were diagnosed after the pregnancies had been terminated, when prenatal diagnosis indicated the presence of multiple bone fractures and bowing of the long bones. While mental development in the patients who have been followed since birth appears to be normal, physical development is severely affected. A follow-up study of the two patients first identified by Cole and Carpenter in 1987 reported that the young men, 18 at the time of the follow-up, were confined to wheelchairs. They have unusually short stature, severe scoliosis, noticeable deformities of the arms and legs, and low bone mineral density.

Although the number of patients identified with Cole-Carpenter syndrome is too small to allow much generalization, it is likely that the disorder shortens the patient's life expectancy, as children with other forms of OI have reduced life expectancy because of the

possibility of fatal bone fractures, breathing difficulties caused by deformities of the spine and rib cage, and complications caused by infections.

Rebecca J. Frey, PhD

Colitis

Definition

Colitis is a serious, chronic or long-lasting, inflammatory bowel disease (IBD) that is characterized by inflammation and sores on the innermost lining of the large intestine—the colon and rectum.

Description

The two types of colitis—ulcerative colitis (UC) and microscopic colitis—along with Crohn's disease, are the most common IBDs. UC is characterized by open sores (ulcers) on the lining of the colon and rectum that may bleed or produce mucus or pus, as well as by inflammation that causes diarrhea. UC is painful and may lead to potentially life-threatening complications, including malnutrition.

Microscopic colitis is an inflammation of the colon that causes persistent watery diarrhea, and can only be identified by examining colon tissue under a microscope.

UC often runs in families, and susceptibility to the disorder appears to be inherited; nevertheless, most people with UC do not have a family history of the disease. Along with a genetic susceptibility, poor immune system functioning and environmental factors appear to be involved in the development of UC. Certain foods, stress, or emotional distress may trigger or worsen symptoms of UC in some people; however, these triggers do not appear to be involved in the development of UC.

The exact cause of microscopic colitis is unknown. Potential causes include medications or bacterial toxins that irritate the colon, viruses that cause inflammation, or autoimmune disorders, in which the body's immune system attacks healthy tissues.

Genetic profile

The genetic profile of UC is not well-understood. Because its development appears to involve multiple genetic and environmental factors, inheritance patterns are not known. Nevertheless, the risk of UC is increased in individuals with one or more affected family members.

Researchers have identified variants of more than two dozen different genes that may be linked to the development of UC. It has been hypothesized that these gene variants (alleles) affect the protective functioning of the intestinal lining or the body's immune system responses to bacteria that normally reside in the digestive tract. The inner surface of the intestines protects deeper tissues from bacteria and toxins, and a failure in this barrier may trigger an immune response to bacteria or toxins that can

Illustration showing the effects of ulcerative colitis on intestinal walls. (Spencer Sutton/Science Source)

lead to chronic inflammation. In addition to genes that are involved in protecting the intestinal lining, potential UC-associated genes have been identified that affect the maturation and function of immune system T cells that normally protect against infection. Certain gene variants that affect T cells can lead to an overactive immune response or an autoimmune response that results in chronic inflammation. As of 2021, there were 13 molecular genetic tests for UC. Some of these tests involve DNA sequencing of all or part of the protein-coding regions (exons) of an individual's genome to detect variations that are potentially associated with UC. Other tests look for specific changes in the DNA sequence of certain genes, or DNA deletions or duplications.

In 2015, the Genetics Initiative of the Crohn's and Colitis Foundation of America (CCFA) was attempting to identify the exact changes or mutations in specific genes that are associated with IBD risk, with the goal of developing new targeted drugs for IBD treatment. Together, the CCFA Microbiome Initiative and Genetics Initiative have identified IBD-associated genes that affect the types of bacteria that reside in the digestive tract.

Demographics

UC is most common in North America and Western Europe. This may be because of diets that are higher in saturated fats from meat and dairy, sugar, cholesterol, and processed foods. Although these dietary factors do not cause UC, they may contribute to IBD symptoms.

Furthermore, UC prevalence is increasing in other parts of the world, possibly due to the spread of Western-type diets. Estimates of UC in North America range from 37 to 246 cases per 100,000 people, with some estimates as high as 238 cases per 100,000 adults, affecting an estimated 750,000 people. UC affects approximately equal numbers of men and women. It can occur at any age but usually begins between the ages of 15 and 30. It is also more likely to develop in people over age 60. UC affects all races and ethnicities but is much more common in Caucasians and especially in people of Ashkenazi Jewish descent.

Microscopic colitis is more common in women than in men and in people aged 50–70 years. It has been associated with smoking, especially in people aged 16–44 years. Microscopic colitis is more common in people with autoimmune disorders such as thyroid disease, celiac disease, or rheumatoid arthritis.

Signs and symptoms

Symptoms of UC vary depending on the severity of the inflammation and where in the colon it occurs, but most cases have mild to moderate symptoms. About half of UC cases are mild and may be confined to the rectum. About 10% of patients have severe symptoms, which are more likely in patients who develop UC at a younger age. UC frequently begins gradually and worsens over time, although most patients have periods of remission, with no symptoms for weeks or years.

The most common symptoms of UC are abdominal pain and diarrhea with blood or pus. Other symptoms may include the following:

- anemia (low red blood cell count)
- severe tiredness
- weight loss
- loss of appetite
- urgent need for bowel movements
- rectal bleeding
- skin sores
- joint soreness or pain
- growth failure in children
- nausea
- fever
- rashes
- eye irritation

Chronic watery diarrhea is the most common symptom of microscopic colitis. Other symptoms may include the following:

- abdominal pain or cramps
- nausea

- weight loss
- fecal incontinence

Diagnosis

Colitis is usually diagnosed and treated by a gastroenterologist. Personal and family medical histories are taken. The physical exam includes detection of any abdominal swelling or sounds within the abdomen that are heard with a stethoscope. It also includes tapping on the abdomen to identify sites of tenderness or pain. Stool tests are used to rule out diarrhea caused by infection. Blood tests are used to check for anemia, inflammatory markers, and infection. Blood tests can also detect low blood protein (albumin), which is common in people with severe UC.

Colonoscopy and flexible sigmoidoscopy utilize a long, thin, flexible tube with a camera to diagnose UC and rule out other potential causes of symptoms. The colon and rectum are examined for irritation, swelling, ulcers, and polyps. Tissue samples (biopsies) can be removed during these procedures. Since the visualized colon appears normal with microscopic colitis, a biopsy for microscopic examination is necessary for diagnosis.

Treatment and management

The goals of colitis treatment and management are to control symptoms, increase the frequency and duration of remissions, and improve quality of life.

Drugs

A variety of drugs are used to treat colitis symptoms. Many people with colitis continue drug therapy indefinitely. Depending on the severity of the colitis and its location in the large intestine, medications may be administered by mouth, intravenously (IV), as an enema or rectal foam, or as a suppository that dissolves in the rectum and is absorbed.

The following drugs can be used to treat colitis.

- **Aminosalicylates**—such as mesalamine, balsalazide, or olsalazine—contain 5-aminosalicylic acid (5-ASA) for controlling inflammation that causes mild-to-moderate symptoms or for maintaining remission. Oral and rectal aminosalicylates administered by enema or as suppositories are most effective when used in combination.
- **Corticosteroids**—such as prednisone and hydrocortisone—are used for severe symptoms and for patients who do not respond to aminosalicylates. They effectively reduce immune system activity and decrease inflammation, but are not usually prescribed long-term because of serious side effects.

KEY TERMS

Aminosalicylates—Anti-inflammatory medications containing 5-aminosalicylic acid (5-ASA) that are commonly used to treat colitis.

Autoimmune disorders—Conditions caused by inappropriate immune system activity.

Biologics—Pharmaceuticals extracted or semi-synthesized from biological sources.

Colon—The part of the large intestine that connects to the rectum.

Colonoscopy—An examination of the rectum and colon with a long flexible instrument passed through the anus; also used to obtain biopsy samples.

Crohn's disease—A chronic inflammatory autoimmune disease similar to colitis.

Inflammation—An immune system response mediated by tumor necrosis factor that can cause pain and swelling.

Megacolon—Extreme swelling of the colon that is a rare but life-threatening complication of colitis.

Microscopic colitis—A form of colitis that can only be diagnosed by examining tissue under a microscope.

Rectum—The lowermost few inches of the large intestine.

Sigmoidoscopy—Examination of the rectum and lower colon with a flexible instrument passed through the anus; also used to remove polyps and obtain biopsy samples.

T cells—Lymphocytes that originate in the thymus gland and regulate the immune response to infections; variants of genes affecting T cells may be associated with colitis.

Tumor necrosis factor (TNF)—A protein called a cytokine that mediates inflammation throughout the body and activates immune system cells; targeted by biologics for treating colitis.

Ulcerative colitis (UC)—A form of colitis characterized by ulcers in the colon that may bleed and produce pus.

- **Immunomodulators**—such as azathioprine or 6-mercaptopurine—reduce immune system activity and decrease colon inflammation in patients who do not respond to 5-ASA. They can take from several weeks to three months to begin working and may have serious

side effects, including increased risk of infection and certain cancers.

- Biologics—such as adalimumab, golimumab, infliximab, and vedolizumab—decrease inflammation in the colon by inhibiting an immune system protein called tumor necrosis factor (TNF). They are injected or infused intravenously and work very rapidly, but they also increase the risk of infection and certain cancers.
- Acetaminophen can be used for mild pain. Ibuprofen, naproxen, or aspirin may worsen symptoms.
- Antibiotics are used to prevent or treat infections.
- Loperamide can slow or stop diarrhea, but it is usually only used for a short time and cannot be used for very active UC.
- Cyclosporine is used only for severe UC because of its side effects.

Surgery

Surgery to remove the entire colon and rectum is performed when colitis patients also have colon cancer or precancerous cells in the colon, life-threatening complications such as bleeding or megacolon (inflammation that has spread to the deep tissues of the large intestine), or poor responses to medications, severe medication side effects, or a requirement for long-term steroid use. During the surgery, an opening is created in the abdomen that connects to a pouch for collecting fecal waste from the end of the small intestine.

Diet

Because diarrhea and rectal bleeding can cause loss of fluids, nutrients, and electrolytes, nutrition is essential for preventing colitis complications. Deficiencies in iron, magnesium, potassium, calcium, folic acid (folate or vitamin B₉), and other vitamins are fairly common in people with colitis. For many patients, diet is also the most important factor for controlling colitis flare-ups. Keeping a food diary can help people identify foods that appear to make symptoms worse. Important nutrition/dietary factors include the following:

- a low-fat diet
- a variety of fruits and vegetables
- fluids
- five or six small daily meals rather than a few large meals
- magnesium
- vitamin C

People with colitis should avoid the following:

- fats, especially saturated fat and fried or greasy foods

QUESTIONS TO ASK YOUR DOCTOR

- How is colitis diagnosed?
- What causes colitis?
- Do you recommend genetic testing for colitis-associated genes?
- What treatment(s) do you recommend?
- What nutritional/dietary changes should I make?
- What is my prognosis?

- butter, margarine, cream sauces, and pork, which can cause diarrhea if fat absorption by the intestine is incomplete
- beans
- spicy foods
- milk products if lactose intolerant
- high-fiber foods—such as nuts, seeds, corn, and some Chinese vegetables—which can cause abdominal cramping and diarrhea
- sugar
- artificial sweeteners
- chocolate
- alcohol

During colitis flare-ups, patients may experience less discomfort when eating soft, bland foods. They may need to avoid the following:

- high-fiber foods, such as raw fruits and vegetables and whole grains
- gas-producing foods, such as beans, cabbage, onions, and broccoli
- caffeine
- carbonated beverages

Prognosis

There is no cure for colitis, other than surgery to remove the entire colon; however, colitis often can be effectively managed with medications and diet. Complications of severe UC may include the following:

- rectal bleeding from ulcers in the intestinal lining
- dehydration and poor absorption of nutrients
- loss of bone density from corticosteroids
- inflammation from immune system activity in other parts of the body, such as the joints, eyes, skin, or liver

- megacolon—a rare but life-threatening complication in which the deep tissues of the large intestine swell and stop functioning and that usually requires surgical intervention.

Margaret Alic, PhD

Collagenopathy, types II and XI

Definition

Collagenopathy, types II and XI, is a group of genetic disorders that affect the connective tissue—the material between joints and organs. The disorders are caused by defects in either type II or type XI collagen. The conditions are considered together because the two types are components of a particular type of cartilage (hyaline cartilage) in joints, the spine, inner ear, and the jelly-like substance (vitreous body) that fills the inner eyeball. Collagens are complex molecules that give connective tissue strength, structure, and the ability to stretch. There are at least ten subtypes of collagenopathy, types II and XI.

Description

Collagenopathy, types II and XI, is classified as a rare disease by the National Institutes of Health (NIH) since it affects fewer than 200,000 Americans, or less than 1 per 3,000. It is considered a genetic disorder because the genes that encode proteins in the connective tissue have defects or mutations that can be passed from parent to child. Among the subtypes of collagenopathy, types II and XI, are the following:

Achondrogenesis type 2

Achondrogenesis type 2 is a severe disorder that interferes with cartilage and bone development. Symptoms include short arms and legs, a narrow chest with short ribs, and underdeveloped lungs. It causes a lack of bone tissue formation in the spine and pelvis, according to the National Library of Medicine (NLM). Facial abnormalities include a prominent forehead, small chin, and in some cases, a cleft palate (an opening in the roof of the mouth). Also, infants with achondrogenesis type 2 have an enlarged abdomen. Sometimes newborns have hydrops fetalis, an excess buildup of fluids in the fetus.

Czech dysplasia

Czech dysplasia is an extremely rare subtype of collagenopathy, types II and XI, that affects how joints work and bone/skeletal development. The main symptom is joint pain in the hips, knees, shoulders, and spine, to an extent that it can hinder mobility. People generally develop symptoms in adolescence or early adulthood. Czech dysplasia patients frequently have short bones in their third and fourth toes, making their other two toes seem unusually long, according to the NLM. Some people with the condition also have hearing loss that worsens

over time. All 11 known cases of this genetic disorder inherited the mutated gene (*COL2A1*) from a parent with the disease.

Hypochondrogenesis

This disorder is rare but severe, and affects bone development starting in the fetus. Symptoms include a small body, short arms and legs, and abnormal bone development in the spine and pelvis. It is usually fatal at or before birth.

Kniest dysplasia

Kniest dysplasia is a rare bone development disorder characterized by short stature, other bone abnormalities, and problems seeing and hearing. Indications of Kniest dysplasia start at birth and include a short trunk, smaller arms and legs, unusually large joints, and arthritis. There is sometimes pain in the joints that can restrict movement. Other symptoms include a round, flat face with wide-set and bulging eyes; severe nearsightedness; detachment of the retina; and frequent ear infections that can lead to hearing loss. Most cases are caused by new mutations in the *COL2A1* gene and occur in people with no family history of the disease, which is unusual in collagenopathy, types II and XI subtypes.

Otospondylomegapiphyseal dysplasia

Otospondylomegapiphyseal dysplasia (also known as OSMED) is a disorder of the skeletal system. Symptoms include skeletal abnormalities, short stature, enlarged joints, hearing loss, a hole in the roof of the mouth, cleft palate, and distinct facial features such as protruding eyes, a flat nose bridge with an upturned nose and rounded tip, and a small lower jaw. The disease is usually detected at birth. The skeletal abnormalities, mainly to the spine, arms, and legs, usually decrease in severity during childhood. Other problems, including hearing loss, joint pain, and arthritis, continue into adulthood. OSMED is extremely rare and caused by mutations in the *COL11A2* gene that prevent the bones and connective tissues from developing properly, according to the NLM.

Spondyloepimetaphyseal dysplasia, Strudwick type

Spondyloepimetaphyseal dysplasia, Strudwick type, is a genetic disorder that results in short stature, skeletal abnormalities, and vision problems. Symptoms are present at birth and include a short torso, shortened arms and legs, an abnormally curved lower back, flattened vertebrae, breastbone protrusion, upper leg bones that turn inward, and arthritis. This disorder is caused by mutations in the *COL2A1* gene, making it an inherited condition.

Spondyloepiphyseal dysplasia congenita

Spondyloepiphyseal dysplasia congenita is a genetic disorder that is present at birth and disrupts bone growth. Symptoms include short stature, skeletal abnormalities, and problems with hearing and seeing. The disorder affects the spine and the ends of the long bones in the arms. People with the disorder have short stature from birth along with a short trunk, neck, arms, and legs. Their hands and feet are usually of average size. During childhood, a curving of the spine becomes more severe and can cause breathing difficulties and spinal damage.

Spondyloperipheral dysplasia

Spondyloperipheral dysplasia is a genetic disorder that impairs bone development. Symptoms include flattened spinal bones and unusually short fingers and toes (except for the big toe). Other symptoms are short stature, shortened long bones in the arm and legs, feet that point in and down (clubfoot), nearsightedness, hearing loss, and impaired intellect. The disorder is caused by mutations in the *COL2A1* gene that disrupt the normal development of bones and connective tissues throughout the body.

Stickler syndrome

Stickler syndrome is a group of four genetic conditions that is characterized by distinct facial abnormalities, hearing loss, and joint problems, including pain and arthritis. The facial differences include a generally flat-looking face caused by undeveloped bones in the face, a hole in the top of the mouth, a large tongue, and a small lower jaw. These symptoms can lead to eating and breathing difficulties. The disorder is caused by mutations in the *COL2A1*, *COL9A1*, *COL11A1*, and *COL11A2* genes.

Weissenbacher-Zweymuller syndrome

Weissenbacher-Zweymuller syndrome is a genetic disorder that causes short stature in which affected individuals are born with small, underdeveloped jaws, a hole in the roof of the mouth, short arms and legs, dumbbell-shaped arm and leg bones, protruding wide spaced eyes, and incompletely formed back bones. Unlike most other forms of short stature, individuals affected by Weissenbacher-Zweymuller start out being affected by short stature at birth and then have a period of gradual growth and bone change that leads to normal physical development by around the age of five or six.

Risk factors

The primary risk factors for collagenopathy, types II and XI, are:

- One or both parents who have the disorder.
- A family history of the disease.

- Parents that are closely related, such as cousins.
- Parents that are part of a distinct ethnic group, such as Ashkenazi Jews, or are in a geographic community that is rural and isolated, such as areas of low-density population in Afghanistan or Mongolia.
- Parents who do not show symptoms of the disease but carry diseased genes that can be detected through genetic testing. This testing is effective but expensive and is not routinely done in the United States or the rest of the world.

Genetic profile

Types II and XI of collagenopathy are caused by genetic defects that can be passed from parent to child. The defects, or mutations, occur in three specific genes: *COL11A1*, *COL11A2*, and *COL2A1*. These gene mutations disrupt the normal way type II and type XI collagens assemble or reduce the amount of these collagens in the body.

Demographics

Demographics vary between subtypes of the disorder.

- The exact number of achondrogenesis type 2 cases in the United States and the world is not documented. However, the National Library of Medicine (NLM), a branch of the U.S. National Institutes of Health, has combined statistics on this disorder along with hypochondrogenesis, a similar skeletal disorder, that show the two conditions occur in 1 in 40,000 to 60,000 newborns.
- The prevalence of Czech dysplasia is unknown in the United States and the world because it is such an extremely rare disease. As of June 2015, at least 11 families worldwide had been affected with the disorder, with most cases in the Czech Republic.
- Ootospondylomegaepiphyseal dysplasia has been diagnosed in only a handful of families worldwide. The prevalence in the United States and the world is unknown as are the demographics.
- Spondyloepimetaphyseal dysplasia, Strudwick type, is extremely rare with only a handful of cases reported worldwide, making it difficult for researchers to study.
- Spondyloepiphyseal dysplasia congenital is extremely rare, with only about 175 cases reported worldwide. Its incidence and demographics are unknown.
- Spondyloperipheral dysplasia is extremely rare in the United States and world with only a few cases reported worldwide, making it difficult to study.
- Stickler syndrome is not an uncommon disease, affecting 1 in every 7,500 to 9,000 newborns in the

KEY TERMS

Arthritis—An inflammation of one or more joints that causes pain, swelling, stiffness, and limited movement.

Cartilage—A type of connective tissue in the body.

Collagen—Complex molecules that give connective tissue strength, structure, and the ability to stretch.

Connective tissue—The material between the cells of the body that gives tissues form and strength.

Cleft palate—A hole at the top (roof) of the mouth.

Dysplasia—An abnormality in the development of cells within tissue.

Short stature—An abnormally low height.

Stem cells—Cells from which all blood cells are derived.

Vitreous—Describes the jelly-like substance that fills the inner eyeball.

United States and world, according to NML estimates. A study followed 21 known cases in Brazil through 2007.

- Weissenbacher-Zweymuller syndrome is extremely rare, and only a few families with the disease have been reported worldwide.

Signs and symptoms

The symptoms vary between the various subtypes of the disorder but there are a number of common symptoms. These include problems with the bones developing properly that can cause short stature, enlarged joints, a curved spine, and arthritis. Symptoms appear at a young age, often months after birth. Other symptoms include sight and hearing problems, a cleft palate with a small lower jaw, protruding eyes, and a flat nose.

Diagnosis

Diagnosis of collagenopathy, types II and XI, can be made through genetic testing or by bone changes observed on x-ray images. Other factors used in the diagnosis include family history of the disorder, family medical history, and physical examination.

Examination

A physical examination of an infant or child can reveal symptoms such as problems with bone development, short stature, and facial abnormalities, including a cleft palate, small lower jaw, and protruding eyes.

Tests

Genetic testing is the most precise method for detecting the disorder and its subtype. Prenatal testing and newborn screening are also used for diagnosis.

Procedures

The most common procedures are blood tests, ultrasound imaging, and x-ray imaging.

Treatment and management

There is no known way to prevent collagenopathy, types II and XI. There are no treatments or cure for collagenopathy, types II and XI, other than treating specific symptoms, such as medications for joint and other pain, and surgery to correct or lessen the effects of seeing and hearing problems. Also, human growth hormone is sometimes used to treat short stature, although its success is sometimes limited.

Traditional

There are no traditional treatments for collagenopathy, types II and XI.

Drugs

There are no drugs that specifically target collagenopathy, types II and XI. This is because, depending on subtype, the condition is rare to extremely rare and little research has been conducted on it. Medications to treat specific symptoms, such as pain and arthritis, are used.

Alternative

In most cases of collagenopathy, types II and XI, alternative therapies are either not available or have limited use since there are no known vitamins, minerals, herbs, or dietary supplements that can affect this genetic disorder. When pain is involved, therapies such as acupuncture, yoga, and meditation can be useful in older children and adults.

Home remedies

There are no home remedies commonly used to treat the two types of collagenopathy.

Prognosis

Prognosis varies between subtypes. In newborns with hypochondrogenesis, the prognosis is grim. Some fetuses do not survive to birth. Newborns with the condition usually die at birth or soon after due to respiratory failure. Infants who survive after birth are usually reclassified as having a related but milder disorder

QUESTIONS TO ASK YOUR DOCTOR

- What are the chances of my children developing this condition?
- Do you know of any recent research or medical breakthroughs concerning my condition?
- Would alternative or complementary treatments be useful in treating any of my symptoms?
- Are there any current or planned clinical trials or studies of my disorder in which I might be eligible to participate?

(spondyloepiphyseal dysplasia congenita) that hinders bone development. In several subtypes, the disorder is not generally life-threatening. There is little that can be done for short stature since it is caused by genetic defects passed from parent to child. There is cause for hope in finding treatments and cures, and even correcting the defective gene or genes in the womb by using genetic research, including the use of stem cells. Stem cell research is being conducted in North America, Europe, and Asia.

Ken R. Wells

Coloboma

Definition

Coloboma is a congenital genetic disorder that results in a piece of tissue missing in or around the eye. There are multiple types of colobomas, some of which are associated with other congenital genetic disorders.

Description

Coloboma describes a condition wherein a portion of a structure of the eye is absent at birth. The affected part

can be the iris, retina, eyelid, or optic nerve. Colobomas may or may not affect vision, depending on their size and location.

Types of colobomas:

- Iris coloboma is also called a uveal or keyhole coloboma, because the shape of the coloboma appears as the shape of a keyhole or an upside-down pear. The iris is the colored part of the eye. The uvea is the middle layer of the eye. The defect may occur in one eye (unilateral) or in both eyes (bilateral).
- Retinal coloboma. In this disorder, a notch or cleft of the retina or part of the retina is missing. The retina is the light-sensitive tissue at the back of the eye.
- Choroidal coloboma. This condition is similar to a retinal coloboma. The choroid is a structure in the eye that lies between the sclera and the retina.
- Optic nerve coloboma. The optic nerve carries nerve impulses from light entering the eye to the brain. This type of coloboma occurs when a uveal coloboma is large enough to cover the optic nerve and may involve the macula, a structure in the eye that is responsible for visual acuity. Alternately, a bit of optic nerve may be missing so that a defect occurs where the optic nerve meets the retina. This condition is sometimes called morning glory syndrome, because it describes the appearance of the optic nerve, which looks like the inside of a morning glory flower.

Coloboma. (Shutterstock/Alina Loseva)

Genetic profile

Colobomas may be isolated abnormalities in otherwise genetically normal individuals, or they may occur as part of a syndrome associated with other congenital genetic disorders. As isolated findings, they generally arise spontaneously, although sometimes they are associated with an autosomal dominant inheritance pattern, meaning that only one copy of the abnormal gene needs to be present for the disorder to occur. Colobomas can also be inherited in an autosomal recessive pattern in which each parent must contribute a changed (mutated) gene for symptoms to be evident. The condition can also be X-linked, meaning that the changed gene is on a sex chromosome. In the case of females who have two X sex chromosomes, the defect might not show symptoms, while in males who have XY sex chromosomes, an X-linked defect will cause symptoms. Some other genetic disorders thought to contribute to coloboma include cat-eye syndrome, trisomy 13, trisomy 18, Sturge-Weber syndrome, and basal cell nevus syndrome.

Demographics

The condition occurs in about one in 10,000 births, although the condition is thought to be underdiagnosed because it does not always affect vision. Uveal colobomas and eyelid colobomas are most common.

Signs and symptoms

Retinal colobomas affect the choroid (light-impermeable lining consisting primarily of blood vessels) and the retina (the photosensitive lining inside the eye). The extent to which vision is impaired depends on the size of the coloboma and its impact on the optic nerve and macula, the center of the retina where fine discrimination occurs.

A woman's eye displaying coloboma. This defect forms because of a failure of the rudimentary eye to join the optic fissure during embryonic development. (Shvaygert Ekaterina/Shutterstock)

KEY TERMS

Choroid—A vascular membrane that covers the back of the eye between the retina and the sclera and serves to nourish the retina and absorb scattered light.

Iris—The colored part of the eye, containing pigment and muscle cells that contract and dilate the pupil.

Macula—A small spot located in the back of the eye that provides central vision and allows people to distinguish colors and fine visual details.

Optic nerve—A bundle of nerve fibers that carries visual messages from the retina in the form of electrical signals to the brain.

Pupil—The opening in the iris through which light enters the eye.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Sclera—The tough white membrane that forms the outer layer of the eyeball.

A coloboma can appear as a black indentation of varying depth at the edge of the pupil, and it gives the pupil an odd or irregular shape. It may also appear as a split in the iris from the pupil to the edge of the iris.

Symptoms usually present as blurred or decreased vision and an appearance of a hole or odd-shaped pupil in the individual's eye. A smaller coloboma, especially if it is not attached to the pupil, often causes a secondary image to focus on the back of the eye, producing blurred vision or decreased visual sharpness. Colobomas are often associated with other eye problems, such as clouding of the eye (cataract), high pressure in the eye (glaucoma), malformation of the retina, and involuntary eye movements.

Diagnosis

A diagnosis is made by a physical exam and includes a detailed eye examination by an ophthalmologist. The ophthalmologist will also ask the individual when the symptoms were first noticed, determine what part of the eye is affected, determine the size and shape of the dark area in the eye, and ask for reports of any changes in the individual's vision.

Certain tests are often used to diagnose coloboma, including a visual acuity test, a refraction test, and an in-depth history of symptoms.

Treatment and management

Colobomas may be accompanied by other problems that may be neurological or chromosomal in nature, including defects in other parts of the body. Some genetic syndromes include coloboma as part of the disorder's potential findings. More importantly, a specific combination of abnormalities identified by the acronym CHARGE must also be considered when a diagnosis of coloboma is made.

The medical condition known as CHARGE association is a very rare and serious condition. Individuals who have the condition will require attention from several specialists and from an early age. Colobomas are usually one of the findings in individuals with CHARGE. The disorder includes these problems:

- (C)oloboma
- (H)eart defects
- (A)tresia of the choanae, which is a blockage of the nasal passages
- (R)etarded growth and development
- (G)enital hypoplasia, which occurs when the testes do not descend properly
- (E)ar abnormalities

While there is no specific treatment for coloboma, some treatments are available that can manage vision problems associated with the disorder. These include glasses or contact lenses to optimize vision in the least affected eye, use of assisted devices for low vision, sunglasses for individuals whose eyesight is adversely affected by bright light, treating or offering preventative treatment for other eye disorders present, such as eye patching to prevent lazy eye. As of 2020, a few individuals have had improvement in iris coloboma through the use of femtosecond laser-assisted cataract surgery (FLACS). This procedure is quite delicate and not widely available. The National Eye Institute offers genetic testing to families with a member who has a coloboma.

Prognosis

The effects of coloboma can be mild or severe, depending upon the extent and location of the gap or cleft. The gap itself is usually located at the bottom of the eye, but it may occur in the iris, choroid, macula, or optic nerve.

A coloboma of the lens, particularly if it is large, may also include abnormalities of the iris and choroids, which increases the risk of retinal tearing. In severe cases of coloboma, the eye may be reduced in size. This condition is called microphthalmia, a disorder that can arise with or without coloboma.

QUESTIONS TO ASK YOUR DOCTOR

- As a parent, how can I recognize coloboma in my child?
- Does coloboma require medical attention, and, if so, should I see some kind of specialist?
- What treatments are available for coloboma?
- Does coloboma lead to more serious vision problems, such as night blindness or loss of vision?

The specific gene or genes responsible for coloboma have not yet been identified, but research continues throughout the United States, Scotland, and England. Clinical trials for treatments of various types of coloboma are underway. Participation in a U.S. clinical trial is voluntary and at no cost to the participant. All clinical trials receiving U.S. government funding, and some supported by private industry, are posted at <https://www.clinicaltrials.gov>. Foreign trials are listed at <https://www.orpha.net>.

Color blindness

Definition

Color blindness, also called color vision deficiency (CVD), is a group of conditions that affect the perception of color, characterized by the inability to distinguish

Ishihara cards for testing color blindness, invented by Japanese ophthalmologist Shinobu Ishihara (1897–1963). A person with normal vision will be able to see numbers, letters, or designs inscribed in the dots. A person with color blindness may see only dots with no defined image inside. Color blindness is usually caused by an inherited genetic defect in the light-sensitive cells (cones) of the eye. In dichromatism, there is difficulty seeing one of the three primary colors: red, blue, or green. In anomalous trichromatism, there is reduced ability to distinguish certain shades of red and green (usually brighter ones). In the rarer monochromatism, there is no color vision and the world appears in white, black, and grey shades. (Wellcome Images/Science Source)

different colors of the spectrum clearly. The difficulties range from mild to severe. Color blindness is a misleading term, because people with color blindness are not blind. Rather, they tend to see colors in a limited range of hues; a rare few might not see colors at all.

Description

Normal color vision requires the use of specialized receptor cells called cones, which are located in the retina of the eye. There are three types of cones, termed red, blue, and green. Each cone contains a special pigment, called photopigment, that is most sensitive to a particular wavelength of light. The combined input from all three types of cones produces normal color vision. An abnormality or deficiency of any of the types of cones will result in abnormal color vision.

There are three basic variants of color blindness. Red-green color blindness is by far the most common deficiency. Affected persons cannot distinguish well between shades of red and green. They see these colors differently from how most people do, and they may have trouble naming different hues.

Blue-yellow color blindness is an inability to distinguish both blue and yellow, which are seen as white or gray. The condition is quite rare. Red-green and blue-yellow color vision deficiency disrupt the perception of color but do not affect the sharpness of vision.

A total inability to distinguish colors (achromatopsia) is exceedingly rare. These affected individuals view the world in shades of gray. They frequently have poor visual acuity and are extremely sensitive to light (photophobic), which causes them to squint in ordinary light.

Genetic profile

Mutations in the *CNGA3*, *CNGB3*, *GNAT2*, *OPN1LW*, *OPN1MW*, and *OPN1SW* genes are known to cause color vision deficiency. The *OPN1LW* gene makes pigments (L cones) that are more sensitive to light at the red end of the visible spectrum, while the *OPN1MW* gene makes pigments (M cones) that are more sensitive to yellow-green light in the middle of the visible spectrum. As for the *OPN1SW* gene, it makes pigments (S cones) that are more sensitive to blue-violet

light at the end of the visible spectrum. Genetic changes involving the *OPN1LW* and *OPN1MW* genes accordingly lead to an absence of L or M cones or the production of abnormal cones that affect red-green color vision. Mutations of the *OPN1SW* gene leads to the premature destruction of S cones or the production of defective cones, which impairs perception of the color blue and makes it difficult to detect differences between shades of blue and green. As for the *CNGA3*, *CNGB3*, and *GNAT2* genes, their mutation is responsible for achromatopsia.

Demographics

In the United States, red-green color vision defects are the most common form of color vision deficiency. This condition affects males more often than females. Some ten million American men (7% of the male population) either cannot distinguish red from green or see red and green differently from the way most people do. This is the most common form of color blindness, and it affects only 0.4% of women. Blue-yellow color vision

defects affect males and females equally. This condition occurs in fewer than one in 10,000 people worldwide. Complete achromatopsia affects an estimated one in 30,000 people. The condition is much more prevalent among Pingelapese islanders, who live on one of the Eastern Caroline Islands of Micronesia. Some 5% to 10% of this population have a total absence of color vision.

Color blindness is sometimes acquired. Chronic illnesses that can lead to color blindness include Alzheimer's disease, diabetes mellitus, glaucoma, leukemia, liver disease, chronic alcoholism, macular degeneration, multiple sclerosis, Parkinson's disease, sickle cell anemia, and retinitis pigmentosa. Accidents or strokes that damage the retina or affect particular areas of the brain can lead to color blindness. Some medications such as antibiotics, barbiturates, anti-tuberculosis drugs, high blood pressure medications, and several medications that are used to treat nervous disorders and psychological problems may cause color blindness. Industrial or environmental chemicals such as carbon monoxide, carbon

A common test used to detect color blindness. The number "hidden" in the image will not be visible to an individual with red/green color blindness. (Huaji/Shutterstock)

Diagram showing the inheritance of color-blindness genes. X-chromosomes (yellow) and Y-chromosomes (blue) combine at center. The normal color vision allele is a red bar, and the color-blindness allele is a black bar. The male symbol (arrow) and female symbol (cross) show the male and female parents and the offspring (sons and daughters). The cross-table shows the probability for color-blindness in the offspring of a normal woman and color-blind man: half of their sons will be color blind, and half of their daughters will be carriers. This trait is thus classed as X-linked recessive. (Francis Leroy, Biocosmos/Science Source)

disulfide, fertilizers, styrene, and some compounds containing lead can cause loss of color vision. Occasionally, changes can occur in the affected person's capacity to see colors after age 60.

Signs and symptoms

The inability to correctly identify colors is the only sign of color blindness. It is important to note that people with red-green or blue-yellow varieties of color blindness use other cues such as color saturation and object shape or location to distinguish colors. They can often distinguish red or green if they can visually compare the colors. However, most have difficulty accurately identifying colors without any other references. Most people with any impairment in color vision learn colors as do other young children. These individuals often reach adolescence before their visual deficiency is identified.

Diagnosis

There are several tests available to identify problems associated with color vision. The most commonly used is the American Optical/Hardy, Rand, and Ritter pseudoisochromatic test. It is composed of several discs filled with colored dots of different sizes and colors. A person with normal color vision looking at a test item sees a number that is clearly located somewhere in the center of a circle of variously colored dots. A color-blind person is not able to distinguish the number.

The Ishihara test comprises eight plates that are similar to the American Optical Pseudoisochromatic test plates. The individual being tested looks for numbers among the various colored dots on each test plate. Some plates distinguish between red-green and blue-yellow color blindness. Individuals with normal color vision perceive one number. Those with red-green color deficiency

see a different number. Those with blue-yellow color vision see yet a different number.

A third analytical tool is the Titmus II Vision Tester Color Perception test. The subject looks into a stereoscopic machine. The test stimulus most often used in professional offices contains six different designs or numbers on a black background, framed in a yellow border. Titmus II can test one eye at a time. However, its value is limited, because it can only identify red-green deficiencies and is not highly accurate.

Treatment and management

There is no treatment or cure for color blindness. Most color vision-deficient persons compensate well for their abnormality and usually rely on color cues and details that are not consciously evident to persons with typical color vision.

Inherited color blindness cannot be prevented. In the case of some types of acquired color deficiency, if the cause of the problem is removed, the condition may improve with time. But for most people with acquired color blindness, the damage is usually permanent.

Contact lenses

Contact lenses made with millions of gold nanoparticles no bigger than a speck of dust could combat color blindness. These “gold dust” particles filter out certain wavelengths of light so the brain can distinguish different colors, particularly reds and greens, more easily. These contact lenses are discreet and have a slight pink hue. They appear pink (rather than gold)

KEY TERMS

Achromatopsia—The inability to distinguish any colors.

Cones—Receptor cells that allow the perception of colors.

Photophobia—An extreme sensitivity to light.

Photopigment—Pigment that is most sensitive to a particular wavelength of light.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Rod—A photoreceptor that is highly sensitive to low levels of light and transmits images in shades of gray.

because gold in tiny fragments has a small surface area and so, rather than reflecting the whole spectrum of light (which would make it appear gold and shiny), it reflects more red light, which makes the lenses look rose-tinted. Gold particles are used in the lenses because the metal is safe to use in the body. To make the contact lenses, gold particles were mixed into hydrogel polymer, the material used for standard contact lenses. In a lab study, the lenses blocked at least 50% of the light that mixes reds and greens, making it easier to tell the colors apart. These lenses may help some people with color blindness in the same way that tinted glasses do. However, they are not a cure for color blindness.

Color blindness: pedigree analysis chart (Gale)

QUESTIONS TO ASK YOUR DOCTOR

- I have blue-yellow color blindness. What is the long-term prognosis for this condition?
- I would like to participate in a clinical trial on color blindness. Where can I get information about such trials?
- What tests are available to determine whether or not my son is color blind and, if so, what kind of color blindness he may have?

Clinical trials

Clinical trials on color blindness and related conditions are currently sponsored by the National Institutes of Health (NIH) and other agencies. Clinical trial information is constantly updated by NIH, and the most recent information on blindness trials can be found at: <https://www.clinicaltrials.gov/ct2/show/NCT00422721>

Prognosis

Color blindness that is inherited is present in both eyes and remains constant over an individual's entire life. Some cases of acquired color vision loss are not severe, may appear in only one eye, and can last for only a short time. Other cases tend to be progressive, becoming worse with time.

Combined pituitary hormone deficiency

Definition

Combined pituitary hormone deficiency (CPHD) is a group of genetic disorders characterized by deficiencies in multiple hormones produced by the pituitary gland. CPHD is characterized by very slow or delayed growth leading to short stature (dwarfism), and can be caused by mutations (changes) in several different genes.

Diagram of brain (Gale)

Description

The pituitary gland is also called the hypophysis. It is divided into two halves: the anterior (front) and the posterior (back). The anterior pituitary produces six hormones: growth hormone (GH), adrenocorticotrophic hormone (ACTH), thyroid-stimulating hormone (TSH), prolactin, and the gonadotropins follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The posterior pituitary gland produces only two hormones: antidiuretic hormone (vasopressin) and oxytocin. Growth and development occur in response to these various hormones. The forebrain contains a small organ called the hypothalamus that is responsible for releasing hormones in response to the body's needs. GH is produced and released by the anterior pituitary gland in response to the release of growth-hormone-releasing hormone (GHRH). GH then stimulates the liver to produce insulin-like growth factor 1 (IGF1).

CPHD most often involves decreased production of hormones from the anterior pituitary gland. The most common form of CPHD is caused by GH deficiency. During childhood, the arms, legs, and other structures develop in normal proportion to the body but at a decreased rate. CPHD was previously known as pituitary

dwarfism. Panhypopituitarism is the lack of production of all anterior pituitary gland hormones.

Mutations in several different genes can cause CPHD. For example, mutations in the *PROPI* gene are associated with GH, TSH, LH, FSH, prolactin, and sometimes ACTH deficiencies. As a result, *PROPI*-associated CPHD (CPHD2) has wide-ranging effects, in addition to underdevelopment of the pituitary gland and short stature. Mutations in the *POUIF1* gene are associated with GH, TSH, and prolactin deficiencies, whereas LH, FSH, and ACTH are still produced.

Genetic profile

Different types of CPHD are caused by mutations in different genes and are inherited in different patterns.

- CPHD type 1, caused by mutations in the *POUIF1* gene located on the short arm (p) of chromosome 3 at 3p11, is inherited in an autosomal recessive pattern. This means that an individual with CPHD1 has inherited two mutated *POUIF1* genes, one from each parent.
- *PROPI*-related CPHD type 2 is also inherited in an autosomal recessive pattern. *PROPI* is located on the long arm (q) of chromosome 5 at 5q35.3.

- CPHD3 is caused by mutations in the *LHX3* gene located on chromosome 9 at 9q34.3.
- CPHD4 is caused by mutations in the *LHX4* gene located on chromosome 1 at 1q25.2.
- CPHD5 is caused by mutations in the *HESX1* gene on chromosome 3 at 3p14.3.
- CPHD6 is caused by mutations in the *OTX2* gene on chromosome 14 at 14q22.3.
- Mutations in other genes, including *SHH* and *HHIP*, may also cause CPHD.

Demographics

CPHD is estimated to affect 1 person in every 8,000 worldwide.

Signs and symptoms

Children with CPHD are usually small with immature-appearing faces and chubby builds. Growth is slowed and does not follow normal growth-curve patterns. However, other signs and symptoms depend on the type of CPHD and the specific gene mutation(s).

- CPHD1 is characterized by severe growth deficiency from birth and distinctive facial features, including a prominent forehead, a depressed nasal bridge, deep-set

eyes, and a short nose. Short stature is sometimes accompanied by severe intellectual disability.

- CPHD2 is characterized by failure to thrive or growth failure beginning between the ages of nine months and eight years. Secondary sexual development may be delayed, incomplete, or absent, and is accompanied by infertility. Without treatment, males usually have a small penis and testes. Females usually require hormone replacement therapy to undergo sexual development.
- In addition to pituitary dysfunction, children with CPHD6 may have abnormally small eyes (microphthalmia).

Diagnosis

The primary diagnostic symptom of CPHD is short stature. Sometimes a hand is x-rayed to compare “bone age” with the child’s chronological age. Affected children’s bone age is usually two or more years behind chronological age. This means that a ten-year-old child will have bones that appear to be those of an eight-year-old.

However, measuring the levels of GH, TSH, LH, FSH, prolactin, and ACTH establishes the diagnosis of CPHD. Underdevelopment or abnormal development of

Pituitary dwarfism: pedigree analysis chart (Gale)

KEY TERMS

Adrenocorticotrophic hormone (ACTH)—A pituitary hormone that acts on cells of the adrenal cortex to produce male sex hormones and hormones that control water and mineral balance in the body.

Antidiuretic hormone (vasopressin)—A hormone that acts on the kidneys to regulate water balance.

Follicle-stimulating hormone (FSH)—A hormone that stimulates estrogen production in females and sperm production in males.

Gonadotropins—Hormones, such as follicle-stimulating hormone, that stimulate the gonads.

Growth hormone (GH)—A hormone that stimulates growth. Also called somatotropin.

Hormone—A chemical messenger produced by the body that regulates specific bodily functions such as growth, development, and reproduction.

Luteinizing hormone (LH)—A hormone secreted by the pituitary gland that regulates the menstrual cycle and triggers ovulation in females. In males it stimulates the testes to produce testosterone.

Oxytocin—A hormone that stimulates uterine contractions during childbirth and the secretion of breast milk.

Panhypopituitarism—Generalized deficiency of all of the anterior pituitary hormones.

Pituitary gland—A small gland at the base of the brain that is responsible for releasing many hormones, including luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Prolactin—A hormone that helps the breast prepare for milk production during pregnancy.

Puberty—The stage of development when the gonads begin to function and secondary sexual characteristics begin to appear.

Thyroid-stimulating hormone (TSH)—A hormone that stimulates the thyroid gland to produce hormones that regulate metabolism.

the pituitary gland can be seen with magnetic resonance imaging (MRI).

Genetic testing may be available if the parental CPHD-related mutations are known. Molecular genetic testing of younger siblings of an affected child allows for early diagnosis and treatment. In any case, younger siblings should be monitored for growth delays. Prenatal genetic testing may also be possible if the relevant mutations have been identified.

QUESTIONS TO ASK YOUR DOCTOR

- What type of combined pituitary hormone deficiency does my child have?
- What caused my child's disorder?
- Is genetic testing for combined pituitary hormone deficiency available for other family members?
- Is prenatal testing available for combined pituitary hormone deficiency?
- What type of hormone replacement therapy will my child need?

Treatment and management

Treatment of CPHD is directed by a pediatric endocrinologist and depends on the hormones that are deficient.

- GH deficiency is treated with GH injections until about age 17. Treatment must be initiated before the child's growth plates have fused.
- TSH is replaced with oral L-thyroxine.
- A limited course of testosterone is used to treat micropenis in male infants with LH and FSH deficiencies.
- For induction of secondary sexual characteristics and puberty, males are treated with monthly injections of testosterone enanthate beginning at 12–13 years of age, and females are treated with estrogen beginning at 11–12 years, and later by cycling with estrogen and progesterone.
- Treatment with gonadotropins can restore fertility in both males and females.
- ACTH deficiency is treated with oral hydrocortisone.

Prognosis

Prognosis depends on the type of CPHD, but in many cases, hormone treatments can lead to near-normal growth, although adults are usually of short stature. Sexual development and fertility are usually possible. However, it can be difficult to balance the levels of the different hormones in the absence of pituitary function, and panhypopituitarism can be particularly difficult to manage. Furthermore, some types of CPHD cause a variety of other medical problems.

Computational genomics

Definition

Computational genomics involves using computer-based mathematical and statistical calculations to analyze genomes. This analysis can help researchers find genes, investigate systems, compare the genomes of different species, diagnose disease, and do many other things.

Description

Huge amounts of data are collected in the study of genomics. Sequencing just one person's whole genome generates approximately 300 gigabytes of raw data. Analysis of this genome produces an additional 100 gigabytes of data. It has been estimated that we will sequence the DNA of more than 100 million genomes by the year

Human genome project computers that record DNA sequencing. Genes are lengths of DNA (deoxyribonucleic acid) that perform specific tasks within an organism. Human DNA has around 3 billion base pairs, divided into more than 100,000 genes. (James King-Holmes/Science Source)

2025, which equates to about 20 billion gigabytes of raw data. Much of this sequencing data will be analyzed as part of pharmaceutical and national population studies.

Analysis of all these data requires a significant amount of computing power and sophisticated mathematical techniques and has led to many advances in the field of computational genomics. This field connects the disciplines of genomics, mathematics, statistics, computer science, and engineering.

Computational genomics uses

Computational genomics is used in gene discovery, diagnosis of disease, personalizing medicine, and managing infectious diseases.

Gene discovery

Computational genomics has been critical for the discovery of genes and their link to disease. The Human Genome Project, which ended in 2003, was the first large-scale, international computational genomics research project. It used computational genomics to sequence the DNA of human genomes and identify the function and location of genes found on the genome. Since then, many countries have launched large-scale population computational genomics projects. For example, in 2018 the UK finished sequencing for the 100,000 Genomes project. This project sequenced 100,000 genomes from people with rare genetic disease or cancers. The goal of this project is to study the genetic causes, diagnosis, and treatment of diseases and find new targeted medicines.

KEY TERMS

Cell—A building block that provides structure to the body and performs all the functions of the body. Cells contain genetic information and can copy themselves. The four main types of cells are the bases of skin, nerve, muscle, and connective tissue.

DNA (deoxyribonucleic acid)—The genetic material that contains the instructions for creating proteins.

DNA base—One unit in a DNA sequence. The four DNA bases are adenine (A), guanine (G), thymine (T), and cytosine (C). The sequence of these bases is the genetic code that contains the instructions for creating proteins.

DNA sequence—The sequence of DNA bases that contains the instructions for creating proteins. A three-base sequence in the DNA contains the instructions for making a particular amino acid. For example, CGC codes for the amino acid alanine. Proteins are made up of one or more amino acids strung together. The instructions for a particular protein are made up of a number of three base sequences. Because DNA is double-stranded, it has two complementary sequences where the bases pair up together. C always pairs with G, and A always

pairs with T. One example of double-stranded DNA sequence for alanine is GCG/CGC.

Gene—A sequence of bases in a DNA sequence that contains the instructions for one protein.

Genome—The complete set of genetic instructions of an organism.

Genomics—The study of the structure, function, and evolution of genomes and how they interact with each other and the environment.

Mitochondrial genome—The DNA (genetic material) found in the mitochondria. The mitochondrial genome contains the instructions for about 37 genes. These genes produce proteins that help the mitochondria function. Mitochondrial DNA is only passed from the mother to her offspring.

Pathogenic variant—Any change in the sequence of a genome that causes disease.

RNA (ribonucleic acid)—The genetic material that is involved in creating proteins.

Sequence (verb)—To determine the sequence of bases in genetic material like DNA or RNA.

Variant—A change in the sequence of a genome.

The NIH has launched a similar project called the Whole Genome Sequencing Project, which has sequenced over 90,000 genomes and aims to sequence 120,000 more. The goal of this project is to identify genetic variations that increase or decrease the risk of heart, lung, blood, and sleep disorders.

Personalized medicine

The DNA sequence of the genome of each person is unique, which means that different people respond differently to different treatments. Personalized medicine customizes treatments based on an individual's genome. Computational genomics has been critical for advances in personalized medicine. Pharmacogenomics and targeted therapies are two examples of personalized medicine.

Pharmacogenomics studies how certain gene variations affect the safety of certain medications and how well they will work. Advances in this field, fueled by computational genomics, have led to genetic tests that can help doctors choose the optimal medication and best dose for a patient. For example, gene variations involving the *CYP2D6* gene can influence the metabolism of codeine into morphine. People who have a duplication in this gene are called

ultrarapid metabolizers. They turn codeine into morphine at a more rapid rate and make greater amounts of morphine. They are at greater risk for overdose if they use codeine and may have serious problems as a result. Breastfeeding mothers with this variation who use codeine are at increased risk of providing excessive amounts of morphine to their babies, which can result in serious breathing problems and even death. People with another variant in *CYP2D6* do not metabolize codeine very well, and they may need to use an alternative pain reliever.

Targeted drug therapies for cancer have been developed using computational genomics. They target specific genes and proteins based on variations found in an individual genome. For example, 20% to 25% of women with breast cancer produce too much HER2 protein. This protein causes the tumor cells to grow more rapidly. These women can benefit if they are given the antibody trastuzumab along with their chemotherapy.

Diagnosis

Diagnosing genetic disease is very complex. There are at least 7,000 known genetic diseases caused by variations in single genes. There is a lot of overlap in

symptoms amongst these diseases, and variations in different genes can cause the same disorder in different people. There are also complex conditions like cardiovascular disease, asthma, and cancer where multiple genes and environmental factors play roles. Early diagnosis of genetic disease relied on evaluation of the symptoms. Later, limited testing that looks for large changes in the chromosomes and genetic testing that looks for variants in specific genes were added to help make or confirm the diagnosis. These approaches can be very time-consuming. For example, one study found that using these approaches, the average time to make the diagnosis of myotonic dystrophy, a muscle-wasting disease, was 14 years.

Next-generation sequencing approaches, such as whole genome sequencing and whole exome sequencing, can help to expedite the diagnosis. Whole genome sequencing looks for variants in the whole genome. It looks for variants in the parts of the genome that contain the genes. The challenge with these approaches is that they generate a lot of data that needs to be analyzed. Whole exome sequencing, for example, generates approximately 30,000 variants, and whole genome sequencing generates even more. It can be challenging to filter through all of these variants to find the one that might explain the disease. To help find this needle in the haystack, researchers have developed computational genomics tools. For example, some tools filter out common variants and predict how likely they will be to cause the disease. There are also many large databases that link specific variants with specific diseases. Computer programs have also been developed to help match an individual's symptoms with variants that might explain them.

Infectious diseases

Sequencing of the genomes of viruses and bacteria can help determine the cause of an infection and help manage outbreaks and pandemics like COVID-19. Sequencing can also help provide information about which treatments might be most effective and help with the development of new treatments.

Researchers around the world have been sharing large amounts of genomic data and using computational genomics to help control the COVID-19 pandemic. New computational tools, such as those for the detection and analysis of SARS-CoV-2-genomes, were created as the result of this pandemic. Computational genomics was also used to identify and analyze new medicines and other treatments for COVID-19.

RNA and mitochondrial DNA genomes

Most computational genomics research to date has focused on analyzing the DNA genome. Newer research

QUESTIONS TO ASK YOUR DOCTOR

- Could whole genome or exome sequencing help diagnose what is wrong with my child?
- Would sequencing my RNA along with my DNA help with my diagnosis?

is investigating both RNA and mitochondrial genomes. RNA (ribonucleic acid) is the genetic material that is involved in creating proteins. The DNA sequence is transcribed into an RNA sequence, which is turned into proteins by machinery in the cell. The mitochondrial genome is DNA found in the mitochondria. Mitochondria, which make energy for the cell, are found in all cells of the body. The mitochondrial genome contains the instructions for about 37 genes, which produce proteins that help the mitochondria function. The mitochondrial genome is only passed from the mother to her offspring through her eggs.

RNA sequencing (RNA-Seq) can be used to show which RNA is present and how much is present in a particular sample. It can help scientists learn which genes are turned on and which are turned off in different cells and how these processes influence disease. RNA-Seq can also help scientists see which changes may indicate disease, and it can be used for diagnosing disease. Variants in genes can often affect which RNA is present and in what amounts. Doing RNA-Seq in combination with DNA sequencing can help to reveal which genetic variant is responsible for disease in an individual. RNA sequencing produces a significant amount of data that can vary significantly. As a result, an increasing number of computational genomics tools are being developed to help make sense of these data.

Variants in the mitochondrial genome can cause disease. Research involving the mitochondrial genome is complex and often results in large amounts of data. Computational genomics tools are being developed to help analyze the data for both research and diagnosis in the clinic.

Cone-rod dystrophy

Definition

The cone-rod dystrophies (CRDs) are a clinically heterogeneous group of progressive retinal degenerative disorders that cause deterioration of the cones and rods in the retina and frequently lead to blindness. They are also known as retinal cone-rod dystrophy or cone-rod degeneration.

KEY TERMS

Amelogenesis imperfecta—A hereditary dental defect characterized by discoloration of the teeth.

Cones—Receptor cells that allow the perception of colors.

Nystagmus—Involuntary rhythmic movement of the eye.

Photophobia—An extreme sensitivity to light.

Photoreceptor cells—Specialized cells that convert light into nerve signals that ultimately get transmitted to the brain through the optic nerve.

Retina—The light-sensitive layer of tissue in the back of the eye that receives and transmits visual signals to the brain through the optic nerve.

Rod—A photoreceptor that is highly sensitive to low levels of light and transmits images in shades of gray.

Description

CRDs are characterized by skin pigmentation abnormality; involuntary rhythmic movements of the eyes (nystagmus); degeneration of vision (optic atrophy); and sensitivity to light (photophobia). CRDs are also sometimes accompanied by amelogenesis imperfecta, an abnormality affecting the teeth. But the common link in all CRDs is a problem with the rod and cone photoreceptors. Cones are used to detect color and fine details, and account for central vision. Rods are required for night and peripheral vision.

Genetic profile

CRDs can be inherited as either an autosomal dominant (ad) or autosomal recessive (ar) trait. In autosomal recessive cone-rod dystrophies (arCRDs), both parents have one copy of the faulty cone-rod dystrophy gene but do not have the disease. Their offspring are affected, not affected, or carriers. In autosomal dominant cone-rod dystrophies (adCRDs), one parent has a single faulty gene. When the affected parent mates with an unaffected and noncarrier mate, the offspring are either affected or not affected, but they are not carriers.

CRDs are genetically heterogeneous. Families showing autosomal dominant, autosomal recessive, and X-linked recessive inheritance have been reported, and a number of causative genes and chromosomal loci have now been identified. Mutations in genes that encode proteins involved in phototransduction, transcription,

metabolic pathways, and other processes affecting retinal function have been associated with CRDs. The *CRX* (*Cone-Rod Homeobox*) gene has been shown to contain mutations that cause adCRDs. This genetic form of CRD is clinically known as cone-rod dystrophy 2 (CRD2). Mutations in the *CRX* gene interfere in the development process of embryonic photoreceptor cells during the early stages of life. The result is abnormal photoreceptor cells with reduced function. Currently, six genes have been shown to be associated with adCRDs: *CRX2*, *3GUCY2D*, *6RIM1*, *7Peripherin/RDS*, *13GUCA1A*, *18*, and *AIPL1*, *20* with more remaining to be discovered. Mutations in *ABCA4* are believed to be the most common cause of arCRD. Other studies have identified additional novel mutations in the *RDH12* (*retinol dehydrogenase 12*) gene associated with early onset CRD. The gene *RPGR* is responsible for two-thirds of the X-linked retinitis pigmentosa (RP) and an as yet undetermined percentage of CRDs.

Demographics

CRDs are rare disorders. The current statistics from Orphanet estimate the prevalence at 1 in 40,000.

Signs and symptoms

The earliest symptom of CRD is loss of night vision that usually begins after the age of 20. The vision loss is progressive and unrelenting. Over the next decade, loss of all vision begins, and by age 50, most people with cone-rod dystrophy have gone completely blind.

Cone-rod dystrophy is occasionally accompanied by amelogenesis imperfecta, which is characterized by abnormally shaped teeth and abnormalities in the tooth enamel.

Diagnosis

The earliest symptom of CRD is decreased visual acuity. However, the diagnosis is usually established upon detection of loss of the peripheral visual fields. Cone-rod dystrophy must be distinguished from RP. In CRD, rods and cones are lost at approximately the same rate. It is further distinguished from RP by the absence of night blindness as a presenting symptom.

Diagnostic gene testing is available for 120 genes identified in 36 different CRDs. Sequence analysis of the entire coding region and deletion/duplication analysis are the most common tests used for diagnosis.

Treatment and management

There is no therapy that stops the evolution of CRDs or restores vision, and the visual prognosis is poor. It has been suggested that people with cone-rod dystrophy may

QUESTIONS TO ASK YOUR DOCTOR

- I have cone-rod dystrophy, but my partner does not. What are the chances that our son will inherit the condition?
- I have read a lot about retinitis pigmentosa. How is my cone-rod dystrophy related to this condition?
- How likely is it that I will completely lose my vision as a result of my cone-rod dystrophy?

be able to slow the progression of their blindness by wearing sunglasses and avoiding bright light. Treatment aims at slowing down the degenerative process, treating the complications, and helping patients to cope with the social and psychological impact of blindness.

In 2008, a novel gene was identified, *NPHP4*, as causing CRD in dogs; in 2017, the gene *IQCB1* was identified as causing CRD in a species of African cat known as *Felis nigripes*. Since CRDs affect humans, felines, and canines, further studies into the complex genetics of this retinopathy has potential for the development of potential therapies.

Prognosis

Studies of individuals thought to have CRD reveal that central vision loss begins in the first decade of life with the onset of night blindness occurring sometime after age 20. Little visual function remains after the age of 50.

Congenital adrenal hyperplasia

Definition

Congenital adrenal hyperplasia (CAH) is a group of common autosomal recessive genetic conditions that result from an abnormality in one of the enzymes required by the adrenal glands to convert cholesterol into the steroid hormones cortisol and aldosterone. CAH is characterized by cortisol and aldosterone deficiencies and overproduction of androgens (male sex hormones), with effects ranging from mild to severe.

Description

The first likely description of CAH occurred in 1865 when anatomist Luigi De Crecchio reported on a cadaver that had what appeared to be a penis with the urinary opening on its underside, and undescended testicles. What was remarkable about this cadaver was that it also had a vagina, a uterus, fallopian tubes, ovaries, and very enlarged adrenal glands. From four years of age until death, this person had lived as a male, although at birth he had been declared a female. He died in his 40s after repeated episodes of vomiting, diarrhea, and prostration. This genetic female with masculinized external genitals

and abnormalities in salt regulation had all the symptoms of severe untreated CAH.

CAH results from an abnormality in one of the enzymes required by the adrenal glands to convert cholesterol into cortisol, aldosterone, and androgens such as testosterone. Cortisol helps the body cope with stress, such as injury or illness, as well as maintain blood sugar levels and suppress inflammation; aldosterone helps to ensure that the body retains normal amounts of salt and fluids, which helps control blood pressure; and androgens such as testosterone are involved in the production of masculine traits such as body hair and the development of male sex organs.

There are many different enzymes necessary for the normal production of cortisol, aldosterone, and testosterone. Each type of CAH results from a deficiency in one of these enzymes. Most cases of CAH (90%–95%) are caused by a deficiency of adrenal steroid 21-hydroxylase, which is involved in the conversion of cholesterol to cortisol and aldosterone but not in the conversion of cholesterol to testosterone. A deficiency or absence of 21-hydroxylase (CAH21) decreases the levels of cortisol and aldosterone, which prompts the body to compensate by forcing the adrenal glands to increase the conversion of cholesterol. This does not significantly increase cortisol and aldosterone levels, but it does increase the levels of testosterone, which is produced by another enzyme. Both men and women normally produce some testosterone, although men typically produce larger amounts.

Increased levels of testosterone can result in premature puberty in males and females and can prevent menstrual periods and increase body hair (hirsutism) in women. Females who produce high levels of testosterone in utero can be born with masculinized external genitals. Decreased levels of cortisol can also result in increased levels of two other hormones: 17-hydroxyprogesterone and androstenedione. Increased levels of 17-hydroxyprogesterone in conjunction with decreased levels of aldosterone can result in the inability of the body to retain normal amounts of salt.

There are three major types of CAH21: (1) the classic salt-wasting form, (2) the classic non-salt-wasting form or simple virilizing form, and (3) the nonclassic (late-onset) form. The classic forms of CAH, if untreated, can result in premature puberty in boys, girls born with an enlarged clitoris or external male genitals, and increased growth in childhood but short adult height in both males and females. The salt-losing form of CAH21 results in reduced levels of salt in the body, which can sometimes result in an adrenal crisis—a life-threatening condition characterized by severe dehydration, very low blood pressure, and vomiting. The nonclassic, or late-onset,

form of CAH21, caused by a partial enzyme deficiency, is milder but can cause an absence of menstruation and increased body hair in women and a low sperm count in men. Some people with nonclassic CAH21 are only diagnosed because of an affected family member.

CAH due to a deficiency in the enzyme 11-beta-hydroxylase (CAH11) also results in excess androgen and virilization, as well as hypertension (high blood pressure) caused by salt retention. CAH11 accounts for 5%–8% of CAH cases. Females with the classic form of CAH11 have external genitalia that are not clearly male or female, but the internal reproductive organs develop normally. Males and females experience early puberty and an early growth spurt that can lead to short stature in adulthood. About two-thirds of individuals with CAH11 have hypertension, usually developing within the first year of life. Females with the nonclassic form of CAH11 have normal genitalia but develop excess body hair and irregular menstruation. Short stature is usually the only sign of nonclassic CAH11 in males. Nonclassic CAH11 does not cause hypertension.

Genetic profile

All types of CAH are autosomal recessive genetic conditions. An autosomal recessive condition is caused by a change (mutation) in both genes of a pair, one inherited from each parent. A person with CAH has mutations in both copies of the gene responsible for producing one of the enzymes involved in steroid production from cholesterol. The parents of a child with CAH are called carriers, since they each possess one mutated CAH gene and one normal CAH gene. Carriers usually do not have any symptoms of disease, since their normal gene produces enough enzyme to prevent symptoms of CAH. Each child born to parents who are both carriers for the same type of CAH has a 25% chance of having CAH, a 50% chance of being a carrier, and a 25% chance of being neither a carrier nor having CAH.

CAH21 results from mutations in the *CYP21A2* gene that produces steroid 21-hydroxylase. *CYP21A2* is located on the short arm (p) of chromosome 6 at 6p21.3. A number of different mutations in *CYP21A2* can reduce or abolish 21-hydroxylase production. The types and combinations of *CYP21A2* mutations at least partially determine the severity of CAH21 symptoms.

CAH11 is caused by mutations in the *CYP11B1* gene that produces 11-beta-hydroxylase. Classic CAH11 is typically caused by mutations that produce 11-beta-hydroxylase that has little or no activity. Nonclassic CAH11 is typically caused by *CYP11B1* mutations that have moderately reduced function.

Rare forms of CAH are caused by mutations in other genes. Lipoid CAH is caused by mutations in the gene encoding steroidogenic acute regulatory protein (*STAR*) located on chromosome 8 at 8p11. CAH due to 17-alpha-hydroxylase deficiency is caused by mutations in the gene encoding steroid 17-monooxygenase (*CYP17A1*).

Demographics

CAH is the most common disorder of the adrenal glands. It affects both females and males of all ethnic backgrounds. CAH21 is the most common form of CAH, accounting for 90%–95% of cases. Approximately 1 person in 60 is a carrier for CAH21. Classic CAH21 occurs in approximately 1 in 15,000 births worldwide. Nonclassic CAH21 is one of the most common genetic disorders, affecting about 1 in 1,000 people overall; however, in some communities it may affect as many as 1 in 20. It is particularly common among Ashkenazi Jews, Hispanics, Italians, and people of Balkan descent. CAH11 accounts for 5%–8% of all CAH cases. It is estimated to occur in 1 in 100,000–200,000 newborns. However, among Moroccan Jews living in Israel, it occurs in about 1 in 5,000–7,000 newborns. The classic form of CAH11 appears to be much more common than the nonclassic form. Lipoid CAH is rare worldwide but is common in Japanese, Korean, and Palestinian Arab populations.

Signs and symptoms

CAH symptoms depend on the particular enzyme deficiency and its extent. CAH can cause congenital masculinization of the female external genitals or feminization of the male genitals, but it does not affect the internal reproductive organs of either males or females. CAH can prevent menstruation in women and increase body hair, and is associated with premature puberty in both males and females.

Classic salt-losing CAH21

The classic salt-losing form is the most severe form of CAH21, resulting from little or no production of 21-hydroxylase. Untreated girls may be mistaken for boys at birth since they are typically born with masculinized external genitals. Their internal sexual organs are, however, normal. Males with untreated CAH21 have normal external genitalia but may experience premature puberty. Signs of puberty such as pubic hair, enlarged penis, deepened voice, and increased muscle strength can occur long before normal puberty, sometimes as early as two to three years of age. An abnormal growth spurt in childhood can prevent later growth, resulting in short

KEY TERMS

Adrenal crisis—A life-threatening complication of salt-losing (salt-wasting) congenital adrenal hyperplasia with 21-hydroxylase deficiency.

Adrenal gland—A triangle-shaped endocrine gland located above each kidney that synthesizes aldosterone, cortisol, and testosterone from cholesterol. The adrenal glands are responsible for salt and water levels in the body, as well as for protein, fat, and carbohydrate metabolism.

Aldosterone—A steroid hormone produced by the adrenal gland that regulates salt and fluid balance in the body and is deficient in congenital adrenal hyperplasia.

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Androgens—Steroid hormones that contribute to the development of male sex organs and male secondary sexual characteristics.

Autosomal recessive—A pattern of genetic inheritance in which two abnormal genes are required to express the trait or disease.

Carrier—An individual who possesses an unexpressed abnormal gene of a recessive genetic disorder.

Carrier testing—Testing performed to determine if a person carries one mutated copy of a particular gene.

Chromosomes—The gene-containing structures found in all of the body's cells; in each normal cell, there are 46 chromosomes that come in 23 pairs.

Congenital—Refers to a disorder that is present at birth.

Cortisol—Hydrocortisone; a glucocorticoid hormone produced by the adrenal glands that mediates various metabolic process and responds to stress; deficient in congenital adrenal hypoplasia.

Deoxyribonucleic acid (DNA)—The genetic material in cells that carries the inherited instructions for growth, development, and cellular functioning.

DNA testing—Genetic analysis of DNA (the genetic component of cells) to determine changes in genes that may cause specific disorders.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Gene—A building block of inheritance that contains the instructions for the production of a particular protein and is made up of a molecular sequence found on a section of DNA. Each gene is found at a precise location on a chromosome.

Glucocorticoids—Corticosteroids, such as cortisol and dexamethasone, that regulate metabolism, along with other functions; medications used to treat congenital adrenal hyperplasia.

Hormone—A chemical messenger produced by the body that is involved in regulating specific bodily functions such as growth, development, and reproduction.

Hypertension—Abnormally high blood pressure in an artery.

In utero—While in the uterus; before birth.

Labia—The two pairs of skin folds that form the externally visible female genitalia. The outer pair is called the labia majora; the labia minora are smaller and lie within the labia majora.

Mutation—An inherited or *de novo* change in the DNA sequence of the genome.

Prenatal testing—Testing for a disease such as a genetic condition in an unborn baby.

Virilization—Masculinization; the development of male sexual characteristics in a female or increased male characteristics in a male caused by excess androgen production.

stature in both males and females. This form of CAH21, if untreated, results in a loss of salt that can trigger an adrenal crisis, which is a life-threatening condition characterized by severe dehydration, very low blood pressure, weakening of the heart muscles, and vomiting. Adrenal crisis typically occurs by 6 to 12 weeks of age. On occasion, salt loss is not noticed until precipitated by an infection in early childhood.

Classic non-salt-losing CAH21

The classic non-salt-losing form of CAH21 results from a low amount of 21-hydroxylase production. In this form of CAH21, enough enzyme is present to prevent abnormally low levels of salt in the body and adrenal crises. Girls are born with slightly masculinized external genitals such as an enlarged clitoris and a partial fusion of the labia. If untreated, they may also experience early

puberty and absence of menstruation. Untreated boys have normal genitals but may have premature puberty. This form of CAH21 can also cause increased growth in childhood and short adult stature.

Nonclassic CAH21

The nonclassic form is the mildest type of CAH21. It results from mildly decreased levels of 21-hydroxylase. Males and females with this form of CAH21 appear normal at birth and do not have salt deficiency. Symptoms may arise in infancy, childhood, or adulthood. Untreated women may have an increase in body hair, irregular or absent menstruation, and/or cysts on their ovaries. Many men have no symptoms. Some men and woman have short stature, severe acne, and decreased fertility.

Diagnosis

Diagnostic testing

Most forms of CAH can be diagnosed by a clinical examination, family history, and the amount of specific hormones in a urine sample. CAH21 can be diagnosed by elevated 17-hydroxyprogesterone in a urine sample. However, CAH21 is best diagnosed with a blood test called an ACTH (adrenocorticotrophic hormone) stimulation test. ACTH is a hormone that stimulates the adrenal glands to convert cholesterol to cortisol. The ACTH stimulation test measures the amount of 17-hydroxyprogesterone in the blood before and after stimulation with ACTH. People with CAH21 have excess production of 17-hydroxyprogesterone after stimulation with ACTH. The ACTH stimulation test can usually identify the type of CAH21.

CAH can also be diagnosed by genetic testing. Detection of a *CYP21* gene alteration can confirm an uncertain diagnosis and can facilitate prenatal diagnosis and carrier testing of relatives.

Carrier testing

Carrier testing may be recommended for relatives of a person with CAH or parents of a child with CAH. Carriers for CAH21 can sometimes be identified through the ACTH stimulation test, although DNA testing is more accurate. If a change in the *CYP21* gene is detected in an affected person, carrier testing can be performed on siblings and parents with an accuracy of greater than 99%. Carrier testing should be considered by anyone whose partner is a known carrier or is affected by CAH. Genetic testing can also identify approximately 95% of carriers for CAH21 who do not have a family history of CAH21.

Prenatal testing

If both parents are carriers for the same type of CAH or one parent is a carrier and the other parent is affected with by the same type of CAH, prenatal testing should be considered. Prenatal testing for CAH21 can only be performed if both parents have detectable mutations in *CYP21A2*. If the relevant gene mutations in the parents have not been identified, prenatal diagnosis of the salt-losing form of CAH21 can be performed by measuring the amount of 17-hydroxyprogesterone in amniotic fluid obtained through amniocentesis. Prenatal testing is especially important for mothers who are undergoing dexamethasone therapy to help prevent their daughters from being born with masculine genitalia. Although treatment must be started before prenatal testing can be performed, treatment can be discontinued if the baby is found to not have CAH21.

Newborn screening

Most states and several foreign countries screen newborns for CAH21 by measuring the amount of 17-hydroxyprogesterone in a drop of blood obtained through a heel prick. The same specimen is tested for thyroid function and various other inherited diseases. Newborn screening is recommended because newborn boys have no outward signs of CAH21 and the death rate from adrenal crisis is high but preventable by early diagnosis and treatment. However, a 2012 study found that routine newborn screening failed to identify approximately 20% of infants with CAH.

Treatment and management

Medications

Most people with CAH are treated with cortisol-like medications called glucocorticoids—oral hydrocortisone for children and prednisone or dexamethasone for adults. In most cases, this therapy is life-long. The goal of treatment is to return cortisol, aldosterone, and testosterone to near-normal levels. Patients with salt-wasting classic CAH21 also require fludrocortisone, an aldosterone-like drug, in order to retain salt and prevent adrenal crises. Babies with the salt-losing form of CAH21 must have salt added to their formula or breast milk. Children and adults do not need salt supplements if they have a high-salt diet. Adrenal crisis is treated by intravenous administration of fluids containing sugars and salt.

Medications usually achieve hormonal balance, but CAH patients can have periods of fluctuating hormones that require modifications in steroid therapy. Because classic CAH can cause short adult stature and high-dose

QUESTIONS TO ASK YOUR DOCTOR

- What are the risks of surgery for my child with congenital adrenal hyperplasia?
- How early in pregnancy (or in utero) can congenital adrenal hyperplasia be diagnosed?
- What treatments are available for congenital adrenal hyperplasia?
- What is the risk that we will have another child with congenital adrenal hyperplasia?
- Is prenatal genetic testing available for congenital adrenal hyperplasia?

glucocorticoids inhibit growth, adjusting steroid doses in the first two years of life is extremely important to maintain near-normal growth and prevent weight gain and/or hypertension. Because of the difficulties in maintaining hormonal balances with medications, clinical trials are testing various new drug combinations. People with the nonclassic form of CAH21 are treated with very-low-dose oral glucocorticoids if required.

Surgery

Adrenalectomy, a surgical procedure to remove the adrenal glands, is a more radical treatment for people with the salt-losing form of CAH21 who have little or no enzyme activity. This surgery allows them to be treated with lower doses of steroids. Adrenalectomy was common before the advent of steroid therapy and is again being recommended for some patients, especially females with little or no enzyme activity and severe virilization that requires high-dose glucocorticoids. Laparoscopic surgery has greatly simplified adrenalectomy, and the life-long replacement hormone doses are lower than those necessary for treating CAH.

Girls born with masculinized genitals may undergo surgery to create female genitals. This surgery is often performed at about 6 to 12 weeks of age. Sometimes an initial surgery is followed by surgery to correct the opening to the vagina when the girl becomes sexually active. Some people believe that any genital surgery should be delayed until individuals are old enough to decide for themselves. Girls with nonclassic CAH do not require genital surgery.

Prenatal treatment

Some mothers who are at risk for having a child with CAH21 take a type of steroid called dexamethasone during

pregnancy. This can often prevent masculinization of the external genitals in female fetuses. To be fully effective, treatment must be started at approximately five to six weeks of gestation, prior to the formation of the external genitals. Treatment can be stopped if prenatal testing shows that the baby is male or an unaffected female; otherwise, the treatment continues throughout the pregnancy. Although this treatment does not appear to have many adverse effects on the fetus, the long-term risks are not known. The mother may experience side effects such as weight gain, fluid accumulation, sugar intolerance, high blood pressure, gastrointestinal problems, and mood swings.

Prognosis

If appropriately treated, the prognosis for CAH, and particularly CAH21, is very good, and most people with CAH have normal lifespans. However, the prognosis for patients with the salt-losing form of CAH21 is dependent on early identification and treatment. Even with treatment, some people with CAH21 have short adult stature and may have decreased fertility. Females treated with feminizing hormones or surgery for masculinized genitals may experience physical and/or psychological difficulties with sexual activity and sexual identity, as well as gender confusion.

Congenital contractural arachnodactyly

Definition

Congenital contractural arachnodactyly (CCA) is a rare genetic disorder of the connective tissue of the skeleton. It is also known as Beals syndrome, Beals contractural arachnodactyly (BCA), or Beals-Hecht syndrome.

Description

Individuals with CCA usually have long, thin fingers and toes that cannot be straightened out because of contractures, resulting in a limited range of motion in the joints of the fingers, hips, elbows, knees, and ankles. They also have unusual external ears that appear crumpled. Contractures of the elbows, knees, and hips at birth are very common. Some babies also have clubfoot, causing one or both feet to be turned in toward each other at the ankles. In most individuals, the contractures improve with time and the clubfoot responds well to physiotherapy.

CCA occurs when fibrillin-2, an important component of the body's connective tissue (the glue and scaffolding of the body, including bones, cartilage, tendons, and fibers) is not made properly. The gene responsible for making fibrillin-2 is called *FBN2* and is located on chromosome 5. Mutations (changes) in the *FBN2* gene result in CCA.

Genetic profile

CCA is caused by a mutation occurring in a gene. Genes are units of hereditary material passed from parents to a child through the egg and sperm. The information contained in genes is responsible for the development of all the cells and tissues of the body. Most genes occur in pairs: one copy of each pair is inherited from the egg cell produced by the mother, and the other copy of each pair comes from the sperm cell of the father.

The gene known as *FBN2* instructs the body how to make fibrillin-2, a specific type of protein. Proteins are substances made in the body that consist of chains of amino acids. Fibrillin-2 is an important part of connective tissue, which provides structural support and elasticity to the body. It is made up of various components, including elastic-like fibers, and fibrillin-2 is thought to play a role in ensuring that the elastic fibers of the connective tissue are assembled properly early in development. Fibrillin-2 binds with other proteins and substances to form microfibrils that form the fibers that provide strength and flexibility to connective tissue. Microfibrils also have a role in regulating growth factors. People with CCA have a mutation in one copy of their *FBN2* gene. As a result, their fibrillin-2 is unable to function properly, resulting in the symptoms of CCA.

CCA is inherited as a dominant condition. Dominant conditions require the presence of only one altered copy of a gene. The mutation in the *FBN2* gene that causes CCA can be inherited from a parent who is also affected with CCA. Individuals with CCA have a 50% chance in each pregnancy to have a child with the condition.

Sometimes CCA cannot be traced back to a parent with the condition. In these cases, the genetic change is said to be a spontaneous mutation. This means that the *FBN2* gene (which functions normally in the parents) mutated in either the sperm of the father or the egg of the mother. If fertilization occurs, the resulting child will have CCA. People with CCA due to a spontaneous mutation can then pass on their altered *FBN2* gene to their children.

Demographics

CCA affects males and females of all ethnic groups. It is a rare condition, estimated to affect fewer than 1 in 10,000 people worldwide.

Signs and symptoms

Besides the general appearance of people with CCA (tall and thin, contractures, with typical crumpled ears), symptoms of the disorder vary from one affected individual to the next. Sometimes the arms are disproportionately long for the person's height. Other less common features may include a small chin, a protruding forehead, and a high arch in the roof of the mouth (palate).

An abnormal bending or twisting of the spine (kyphosis/scoliosis) is seen in about half of individuals diagnosed with CCA and can occur in early infancy. This bending and twisting of the spine tends to worsen over time. Some individuals may also have an abnormal

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman’s abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Chromosome—A microscopic threadlike structure found within each cell of the body that consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Connective tissue—Tissues responsible for support throughout the body, including cartilage, bone, fat, and tissue underlying skin and supporting organs, blood vessels, and nerves.

Contracture—A tightening of muscles that prevents normal movement of the associated limb or other body part.

FBN2—The gene that encodes fibrillin-2; mutations in this gene can cause congenital contractural arachnodactyly.

Fibrillin-2—A protein that helps form microfibrils that provide strength and flexibility to connective tissue.

Kyphosis—An abnormal outward curvature of the spine, with a hump at the upper back.

Mitral valve prolapse—A heart defect in which one of the valves of the heart (which normally controls blood flow) becomes floppy. Mitral valve prolapse may be detected as a heart murmur, but there are usually no symptoms.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual or manifest as disease and can be transmitted to offspring.

Proteins—Important building blocks of the body, composed of amino acids and involved in the formation of body structures and controlling the basic functions of the human body.

Scoliosis—An abnormal side-to-side curvature of the spine.

indentation or protrusion of their chest wall. Decreased muscle bulk, especially in the lower legs, is also a common sign of CCA.

Less common symptoms of CCA include heart and eye problems. The most frequent heart problem involves one of the heart valves (mitral valve prolapse) and may necessitate medication prior to dental or other surgeries so as to prevent infection. More serious heart problems may occur but are rare. Rarely, the aorta—the major blood vessel carrying blood away from the heart—may be enlarged. This condition usually requires medication to prevent further enlargement, or occasionally surgery. A small number of individuals with CCA are nearsighted and require eyeglasses.

Diagnosis

The diagnosis of CCA is based on the presence of specific characteristics. The diagnosis is suspected in anyone with the typical features of CCA, such as tall, slender stature; contractures of many joints including the elbows, knees, hips, and fingers; abnormal curvature of the spine; decreased muscle bulk; and crumpled ears. Genetic testing is available for CCA.

Testing during pregnancy (prenatal diagnosis) to determine whether the unborn child of at-risk parents may be affected may be available. Using a procedure called amniocentesis, fluid surrounding the developing fetus is removed, and cells from the fluid are submitted for genetic testing. However, because of the relatively mild nature of the condition in most individuals, prenatal diagnosis may not be requested.

Treatment and management

There is no cure for CCA. Management of the disorder usually involves physiotherapy in early childhood to increase joint mobility and to lessen the effects of low muscle bulk. The contractures have been known to spontaneously improve, with surgery sometimes required to release them.

The abnormal curvature of the spine tends to worsen with time. A bone specialist should be consulted for advice on the appropriate treatment. Some individuals may require a back brace and/or surgery to correct the curvature.

A heart specialist should be consulted because some individuals with CCA have heart defects. An ultrasound

QUESTIONS TO ASK YOUR DOCTOR

- Can you explain why my child's CCA is a genetic disorder?
- Will surgery be necessary to deal with the condition and if so, what risks are associated with the surgery?
- What other kinds of treatment will my child require for CCA?
- What effect will my child's CCA have on lifespan?
- What are my risks of having another child with CCA?

of the heart usually can assess any abnormalities. Medications may be used to treat some types of heart problems. An eye specialist should also be consulted because of the possibility of eye problems such as myopia (nearsightedness). Prescription eyeglasses may be necessary.

Individuals with CCA and their families may benefit from genetic counseling for information on the condition and the risk of CCA in future pregnancies.

Prognosis

There tends to be gradual improvement in the joint contractures with time. The abnormal spinal curvature tends to get worse over time and may require bracing or surgery. The lifespan of individuals with CCA is not affected.

Congenital heart disease

Definition

Congenital heart disease, also called congenital heart defect, includes a variety of malformations of the heart or its major blood vessels that are present at the birth of a child.

Description

Congenital heart disease occurs when the heart or blood vessels near the heart do not develop properly before birth. Some infants are born with mild types of congenital heart disease, but most need surgery in order to survive. Patients who have had surgery are likely to experience other cardiac problems later in life.

Most types of congenital heart disease obstruct the flow of blood in the heart or the nearby vessels or cause an abnormal flow of blood through the heart. Rarer types of congenital heart disease occur when the newborn has only one ventricle, when the pulmonary artery and the aorta come out of the same ventricle, or when one side of the heart is not completely formed.

Patent ductus arteriosus

Patent ductus arteriosus refers to the opening of a passageway—or temporary blood vessel (ductus)—to carry the blood from the heart to the aorta before birth,

Various heart defects. (Shutterstock/N.Style)

allowing blood to bypass the lungs, which are not yet functional. The ductus should close spontaneously in the first few hours or days after birth. When it does not close in the newborn, some of the blood that should flow through the aorta then returns to the lungs. Patent ductus arteriosus is common in premature babies but rare in full-term babies. It has also been associated with mothers who had German measles (rubella) while pregnant.

Hypoplastic left heart syndrome

Hypoplastic left heart syndrome, a condition in which the left side of the heart is underdeveloped, is rare, but it is the most serious type of congenital heart disease. With this syndrome, blood reaches the aorta, which pumps blood to the entire body only from the ductus, which then normally closes within a few days of birth. In hypoplastic left heart syndrome, the baby seems normal at birth, but as the ductus closes, blood cannot reach the aorta and circulation fails.

Obstructive defects

When heart valves, arteries, or veins are narrowed, they partly or completely block the flow of blood. The most common obstructive defects are pulmonary valve stenosis, aortic valve stenosis, and coarctation of the aorta. Bicuspid aortic valve and subaortic stenosis are less common.

Stenosis is a narrowing of the valves or arteries. In pulmonary stenosis, the pulmonary valve does not open

properly, forcing the right ventricle to work harder. In aortic stenosis, the improperly formed aortic valve is narrowed. As the left ventricle works harder to pump blood through the body, it becomes enlarged. In coarctation of the aorta, the aorta is constricted, reducing the flow of blood to the lower part of the body and increasing blood pressure in the upper body.

A bicuspid aortic valve has only two flaps instead of three, which can lead to stenosis in adulthood. Subaortic stenosis is a narrowing of the left ventricle below the aortic valve, which limits the flow of blood from the left ventricle.

Septal defects

When a baby is born with a hole in the septum (the wall separating the right and left sides of the heart), blood leaks from the left side of the heart to the right, or from a higher pressure zone to a lower pressure zone. A major leakage can lead to enlargement of the heart and failing circulation. The most common types of septal defects are atrial septal defect, an opening between the two upper heart chambers; and ventricular septal defect, an opening between the two lower heart chambers. Ventricular septal defect accounts for about 20% of all cases of congenital heart disease in the United States.

Cyanotic defects

Heart disorders that cause a decreased, inadequate amount of oxygen in blood pumped to the body are called

cyanotic defects. These defects, including truncus arteriosus, total anomalous pulmonary venous return, tetralogy of Fallot, transposition of the great arteries, and tricuspid atresia, result in a blue discoloration of the skin due to low oxygen levels. About 10% of cases of congenital heart disease in the United States are tetralogy of Fallot, which includes four defects. The major defects are a large hole between the ventricles, which allows oxygen-poor blood to mix with oxygen-rich blood, and narrowing at or beneath the pulmonary valve. The other defects are an overly muscular right ventricle and an aorta that lies over the ventricular hole.

In transposition (reversal of position) of the great arteries, the pulmonary artery and the aorta are reversed, causing oxygen-rich blood to re-circulate to the lungs while oxygen-poor blood goes to the rest of the body. In tricuspid atresia, the baby lacks a tricuspid valve, and blood cannot flow properly from the right atrium to the right ventricle.

Other defects

Ebstein's anomaly is a rare congenital syndrome that causes malformed tricuspid valve leaflets, which allow blood to leak between the right ventricle and the right atrium. It also may cause a hole in the wall between the left and right atrium. Treatment often involves repairing the tricuspid valve. Ebstein's anomaly may be associated with maternal use of the psychiatric drug lithium during pregnancy.

Brugada syndrome is another rare congenital heart defect that appears in adulthood and may cause sudden death if untreated. Symptoms, which include rapid, uneven heartbeat, often appear at night. Scientists believe that Brugada syndrome is caused by mutations in the gene *SCN5A*, which involves cardiac sodium channels.

Infants born with DiGeorge sequence can have heart defects such as a malformed aortic arch and tetralogy of Fallot. DiGeorge is the most common microdeletion syndrome and is often caused by mutations in genes in the region 22q11.2.

Williams-Beuren syndrome or Williams syndrome (WS) is a gene deletion syndrome caused by deletion at 7q11.23. It is characterized by specific cardiovascular defects such as vascular stenoses and elastin arteriopathy, distinctive personality characteristics, growth abnormalities, connective tissue and skeletal abnormalities, and endocrine abnormalities including infantile hypercalcemia, hypercalciuria, hypothyroidism, and early puberty.

Jacobsen syndrome (JS) is gene deletion syndrome involving deletions from 11q23 to the telomere. More than half of affected individuals have congenital heart disease along with growth retardation, cognitive and behavioral problems, recurrent infections, immune deficiency, and

Illustration of a defective heart viewed from behind. The defect is a hole in the wall between the two ventricles. This results in deoxygenated blood (blue arrow) mixing with oxygenated blood (red arrow), which can lead to pulmonary hypertension and breathlessness. (Bo Veisland/Science Source)

blood, ophthalmologic, gastrointestinal, and genitourinary problems.

The 1p36 deletion syndrome is the second most common deletion syndrome, and about 90% of affected individuals have severe intellectual disability and behavioral problems along with brain abnormalities and structural heart defects, including septal defects, valvular abnormalities, tetralogy of Fallot, coarctation of the aorta, stenosis of the right ventricle, and Ebstein's anomaly.

1q21.1 deletions are associated with microcephaly, mild intellectual disability, short stature, eye abnormalities and hearing loss in addition to many types of congenital heart disease.

8p23.1 deletions are associated with diaphragmatic hernia, growth impairment, microcephaly, behavioral problems (including hyperactivity and impulsivity), mild to moderate intellectual disability, and developmental delays as well as congenital heart disease.

Marfan syndrome is a connective tissue disorder that causes tears in the aorta. Since the disease also causes

KEY TERMS

Aorta—The main artery located above the heart, which pumps oxygenated blood out into the body. Many congenital heart defects affect the aorta.

Congenital—Referring to a disorder that is present at birth.

Cyanotic—Marked by bluish discoloration of the skin due to a lack of oxygen in the blood. It is one of the types of congenital heart disease.

Ductus—The blood vessel that joins the pulmonary artery and the aorta. When the ductus does not close at birth, it causes a type of congenital heart disease called patent ductus arteriosus.

Electrocardiograph (ECG, EKG)—A test used to measure electrical impulses coming from the heart in order to gain information about its structure or function.

Hypoplastic—Incomplete or underdevelopment of a tissue or organ. Hypoplastic left heart syndrome is the most serious type of congenital heart disease.

Nuchal translucency—A pocket of fluid at the back of an embryo's neck visible via ultrasound. When thickened, it may indicate that the infant will be born with a congenital heart defect.

Septal—Relating to the septum, the thin muscular wall dividing the right and left sides of the heart. Holes in the septum are called septal defects.

Stenosis—The constricting or narrowing of an opening or passageway.

excessive bone growth, most Marfan syndrome patients are over six feet tall. In athletes, and others, it can lead to sudden death. Researchers believe the defect responsible for Marfan syndrome is found in gene *FBNI*, on chromosome 15.

Other syndromes that involve congenital heart defects are caused by single-gene variants (formerly called mutations) that are genetically heterogeneous, which means that an individual variant in more than one gene is capable of causing a similar condition.

Genetic profile

Some of the genes that are responsible for, or associated with, congenital heart defects have been identified; others are as yet unknown. Single-gene disorders are responsible for 3% to 5% of congenital heart defects,

and gross chromosomal anomalies and aneuploidy (an abnormal number of chromosomes) are present in 8% to 10% of cases. Pathogenic (disease-causing) copy number variants (involving large insertions or deletions of DNA, greater than 1,000 nucleotides long, that can occur anywhere in the genome) are present in 3% to 25% of persons with congenital heart disease as part of a syndrome, and in 3% to 10% among persons for whom congenital heart disease is the sole problem. When feasible, genetic testing can help families determine the risk that their child will be born with a heart defect.

Demographics

Congenital heart disease is the most commonly occurring birth defect, affecting about one percent of live births. In the United States, about 40,000 infants are born every year with congenital heart disease and about half of these require medical treatment. More than one million people with heart defects are currently living in the United States. It is not yet known why racial and ethnic minorities are disproportionately affected by this congenital heart disease. It is possible that certain variants or genetic loci are more prevalent in certain ethnic or racial groups.

Signs and symptoms

In most cases, the causes of congenital heart disease are unknown. Genetic and environmental factors and lifestyle habits can all be involved. Environmental causes can be identified in many as 30% of cases. The likelihood of having a child with a congenital heart disease increases if the mother or father, another child, or another relative had congenital heart disease or a family history of sudden death. Viral infections, such as German measles, can produce congenital heart disease. Women with diabetes and phenylketonuria also are at higher risk of having children with congenital heart defects. Many cases of congenital heart disease result from the mother's excessive use of alcohol or illegal drugs, such as cocaine, while pregnant. The mother's exposure to certain anticonvulsant and dermatologic drugs during pregnancy can also cause congenital heart disease. There are many genetic conditions, such as Down syndrome, that affect multiple organs and can cause congenital heart disease.

Symptoms of congenital heart disease include shortness of breath, difficulty feeding in infancy, sweating, cyanosis (bluish discoloration of the skin), heart murmur, respiratory infections that recur excessively, stunted growth, and limbs and muscles that are underdeveloped.

Symptoms of specific types of congenital heart disease are as follows:

- Patent ductus arteriosus: quick tiring, slow growth, susceptibility to pneumonia, rapid breathing. If the ductus is small, there are no symptoms.
- Hypoplastic left heart syndrome: ashen color, rapid and difficult breathing, inability to eat.
- Obstructive defects: cyanosis (skin that is discolored blue), chest pain, tiring easily, dizziness or fainting, congestive heart failure, and high blood pressure.
- Septal defects: difficulty breathing, stunted growth. Sometimes there are no symptoms.
- Cyanotic defects: cyanosis, sudden rapid breathing or unconsciousness, and shortness of breath and fainting during exercise.

Diagnosis

Echocardiography and cardiac magnetic resonance imaging are used in the diagnosis of congenital heart disease when it is suggested by the symptoms and physical examination. An echocardiograph will display an image of the heart that is formed by sound waves. It detects valve-related and other heart problems. Fetal echocardiography is used to diagnose congenital heart disease in utero, usually after 20 weeks of pregnancy. Between the 10th and 14th weeks of pregnancy, physicians also may use an ultrasound to look for a thickness at the nuchal translucency, a pocket of fluid in back of the embryo's neck, which may indicate a cardiac defect in 55% of cases. Cardiac magnetic resonance imaging, a scanning method that uses magnetic fields and radio waves, can help physicians evaluate congenital heart disease, but it is not always necessary. Physicians may also use a chest x-ray to look at the size and location of the heart and lungs, or an electrocardiogram (ECG), which measures electrical impulses to create a graph of the heartbeat.

Treatment and management

Congenital heart disease is treated with drugs and/or surgery. Drugs used include diuretics, which aid the baby in excreting water and salts; and digoxin, which strengthens the contraction of the heart, slows the heartbeat, and removes fluid from tissues.

Surgical procedures seek to repair the defect to the greatest extent possible and to restore circulation to as close to normal as possible. Sometimes, multiple surgical procedures are necessary. Surgical procedures include arterial switch, balloon atrial septostomy, balloon valvuloplasty, Damus-Kaye-Stansel procedure, Fontan procedure, pulmonary artery banding, Ross procedure, shunt procedure, and venous switch or intra-atrial baffle.

QUESTIONS TO ASK YOUR DOCTOR

- What are some of the physical characteristics of congenital heart disease?
- What kinds of tests are needed to confirm a diagnosis of congenital heart disease?
- What types of surgery may be necessary to treat various forms of congenital heart disease?
- What lifestyle adaptations (such as increased or decreased levels of exercise) should we consider for a child born with congenital heart disease?

Arterial switch, to correct transposition of the great arteries, involves connecting the aorta to the left ventricle and connecting the pulmonary artery to the right ventricle. Balloon atrial septostomy, also done to correct transposition of the great arteries, enlarges the atrial opening during heart catheterization. Balloon valvuloplasty uses a balloon-tipped catheter to open a narrowed heart valve, improving the flow of blood in pulmonary stenosis. It is sometimes used in aortic stenosis. Transposition of the great arteries can also be corrected by the Damus-Kaye-Stansel procedure, in which the pulmonary artery is cut in two and connected to the ascending aorta and the farthest section of the right ventricle.

For tricuspid atresia and pulmonary atresia, the Fontan procedure connects the right atrium to the pulmonary artery directly or with a conduit, and the atrial defect is closed. Pulmonary artery banding, narrowing the pulmonary artery with a band to reduce blood flow and pressure in the lungs, is used for ventricular septal defect, atrioventricular canal defect, and tricuspid atresia. Later, the band can be removed, and the defect can be corrected with open-heart surgery.

To correct aortic stenosis, the Ross procedure grafts the pulmonary artery to the aorta. For tetralogy of Fallot, tricuspid atresia, or pulmonary atresia, the shunt procedure creates a passage between blood vessels, sending blood into parts of the body that need it. For transposition of the great arteries, venous switch creates a tunnel inside the atria to redirect oxygen-rich blood to the right ventricle and aorta, and venous blood to the left ventricle and pulmonary artery.

When all other options fail, some patients may need a heart transplant. Children with congenital heart disease require lifelong monitoring, even after successful surgery. The American Heart Association recommends regular dental check-ups and the preventive use of antibiotics to

protect some, but not all, patients with congenital heart disease, such as those with prosthetic heart valves, unrepaired cyanotic congenital heart defects, and cardiac transplant with valve regurgitation due to an abnormal valve from heart infections, or endocarditis.

Prognosis

The outlook for children with congenital heart disease has improved markedly in the past two decades. Many types of congenital heart disease that would have been fatal can now be treated successfully. Research on diagnosing and repairing heart defects when the fetus is in the womb enables physicians to correct some defects before birth. Promising new prevention methods and treatments include genetic screening and the cultivation of cardiac tissue in the laboratory that could be used to repair congenital heart defects.

Congenital hypothyroid syndrome

Definition

Congenital hypothyroid syndrome is a condition in which a child is born with a deficiency in thyroid gland activity or thyroid hormone levels.

Description

The thyroid gland is a small gland in the front of the neck that secretes hormones called thyroxine (T₄) and triiodothyronine (T₃) into the bloodstream. Some of the T₄ is converted into T₃ by the liver and kidney. These thyroid hormones help regulate a large number of processes. A deficiency in the level of these hormones can affect the brain, heart, muscles, skeleton, digestive tract, kidneys, reproductive function, blood cells, other hormone systems, heat production, and energy metabolism.

In most cases of congenital hypothyroidism, the thyroid gland is either completely absent or severely underdeveloped. Sometimes thyroid tissue is located in ectopic, or abnormal, locations along the neck.

Other abnormalities can lead to congenital hypothyroidism including the following:

- abnormal synthesis of thyroid hormones
- abnormal synthesis of thyroid-stimulating hormone (TSH) or thyrotropin-releasing hormone (TRH), which are regulatory hormones that affect the production of thyroid hormones
- abnormal response to thyroid hormones, TSH or TRH
- inadvertent administration of harmful drugs or substances to the pregnant mother, possibly resulting in temporary congenital hypothyroidism in the newborn
- dietary deficiency of iodine, a raw component vital to the manufacturing of thyroid hormones

Genetic profile

Most causes of congenital hypothyroidism are not inherited. Some abnormalities in thyroid hormone synthesis (TSH synthesis), or the response to TSH, are inherited in autosomal recessive fashion. This means that both parents have one copy of the changed (mutated) gene but do not have the condition. Abnormal response to thyroid hormones may be an autosomal dominant condition, meaning that only one parent has to pass on the gene mutation in order for the child to be affected with the syndrome.

Demographics

Congenital hypothyroidism occurs in 1 in every 4,000 newborns in the United States. It is twice as common in girls as in boys. The condition is less common in African Americans, and more common in Hispanics and Native Americans.

Signs and symptoms

The signs and symptoms of congenital hypothyroidism are difficult to observe because the mother passes along some of her thyroid hormones to the fetus during pregnancy. Even if the newborn is completely lacking a thyroid gland, it may not be obvious in the early stages of life. Ectopic thyroid tissue may also provide enough thyroid hormones for a short period of time.

Rarely, the affected newborn will exhibit jaundice (yellow skin), noisy breathing, and enlarged tongue. If hypothyroidism continues undetected and untreated, the

KEY TERMS

Congenital—Refers to a disorder that is present at birth.

Ectopic—Tissue found in an abnormal location.

Hypothyroid—Deficiency in thyroid gland activity or thyroid hormone levels.

Jaundice—Yellowing of the skin or eyes due to excess of bilirubin in the blood.

Levothyroxine—A form of thyroxine (T_4) for replacement of thyroid hormones in hypothyroidism.

Myxedema—Swelling of the face, hands, feet, and genitals due to hypothyroidism.

Scintigraphy—Injection and detection of radioactive substances to create images of body parts.

Thyroxine (T_4)—The major thyroid hormone; it has a longer half-life than triiodothyronine.

Triiodothyronine (T_3)—The minor thyroid hormone.

infant may gradually demonstrate feeding problems, constipation, sluggishness, sleepiness, cool hands and feet, and failure to thrive. Other signs include protruding abdomen, slow pulse, enlarged heart, dry skin, delayed teething, and coarse hair. Affected children may also have myxedema, which is swelling of the face, hands, feet, and genitals. Hypothyroidism eventually leads to marked

retardation in physical growth, mental development, and sexual maturation.

Diagnosis

Prompt diagnosis and treatment are critical to avoid the profound consequences of hypothyroidism. The signs and symptoms of hypothyroidism are often subtle in newborns, only to manifest themselves later in life when permanent damage has been done. Before the implementation of screening for hypothyroidism in the

1970s, most children with the disease suffered growth retardation and intellectual disability, as well as neurological and psychological deficits.

Most cases of congenital hypothyroid syndrome are now detected by a screening test performed during a newborn's first few days of life. Every state offers testing, and most states require it. The test for hypothyroidism is part of a battery of standard screening tests designed to diagnose important conditions. A sample of the child's blood is analyzed for levels of thyroxine (T_4), thyroid-stimulating

QUESTIONS TO ASK YOUR DOCTOR

- What are the causes of congenital hypothyroidism?
- What tests will you use to diagnose the disorder in my child?
- What treatments are available for congenital hypothyroidism, how effective are they, and what side effects should we expect from these treatments?
- What factors affect the long-term prognosis of my child's congenital hypothyroidism?

hormone (TSH), or both, depending on the individual state or country. Some states also require a second round of screening performed one to four weeks later.

Once the diagnosis of congenital hypothyroidism is made, other tests can pinpoint the nature of the abnormality. X-rays of the hip, shoulder, or skull often reveal characteristically abnormal patterns of bone development. Scintigraphy is a method by which images of the thyroid gland and any ectopic thyroid tissue are obtained to determine if the thyroid is absent or ectopic. However, treatment should not be delayed for these other tests. Early treatment offers a good probability of normal development.

Treatment and management

Treatment of congenital hypothyroidism requires replacement of deficient thyroid hormones with levothyroxine, an oral tablet form of T_4 . There is no need to directly replace T_3 , since T_4 is converted to T_3 by the liver and kidney. Hypothyroid children usually require more levothyroxine per pound of body weight than hypothyroid adults do. The importance of prompt and adequate treatment cannot be overemphasized. Delays in treatment result in permanent stunting of physical, mental, and sexual development.

Blood levels of T_4 should be checked regularly to ensure appropriate replacement. The blood levels of TSH should also be monitored since TSH is an indicator of the effectiveness of T_4 replacement. As the child develops, the physical growth rate also provides a good measure of treatment.

Prognosis

If congenital hypothyroidism is detected and treated early in life, the prognosis is quite good. Most children will

develop normally. However, the most severely affected infants may have mild intellectual disability, speech difficulty, hearing deficit, short attention span, or coordination problems.

Congenital microcoria

Definition

Congenital microcoria (MCOR) is a rare genetic disorder characterized by unusually small pupils of the eye resulting from the absence or underdevelopment of the

dilator pupillae muscle of the iris. It is associated with extreme myopia (nearsightedness) and juvenile-onset glaucoma. The word “microcoria” comes from two Greek words that mean “small” and “pupil.” Other names for the disorder include congenital miosis and chromosome 13q32 deletion syndrome.

MCOR as a condition is also associated with Pierson syndrome, a genetic disorder characterized by severe kidney disease (congenital nephrotic syndrome) and neuromuscular defects as well as abnormalities of the eye. Pierson syndrome is also called microcoria-congenital nephrotic syndrome.

Description

MCOR by itself is a disorder limited to the eye; that is, it does not affect other body systems. It has been described as a failure of normal development of the anterior chamber of the eye, which is the front portion of the eye between the cornea and the iris. A muscle in the iris known as the dilator pupillae is either underdeveloped or missing altogether; as a result, the pupil cannot dilate normally even when mydriatics (drugs used to prevent the pupil from contracting in bright light, usually given as part of an eye examination) are administered. The average size of the pupil in patients with MCOR is only about 0.8 mm and cannot be dilated beyond 1.4 mm.

In contrast to MCOR, Pierson syndrome involves severe and progressive kidney disease as well as microcoria and other neurological and muscular problems. Patients require lifelong monitoring for kidney function; some suffer from kidney failure within a few weeks or months after birth, while others reach adult maturity before their kidneys fail.

Genetic profile

MCOR has been traced to a deletion on chromosome 13 at 13q32.1. The deletion encompasses two genes: *TGDS*, which has no known function in regard to muscle cells, and *GPR180*, which regulates the growth of smooth muscle cells. The international team of geneticists that identified the deletion suggests that loss of the *GPR180* gene is the cause of congenital microcoria. MCOR is known to be transmitted in an autosomal dominant pattern, which means that only one copy of chromosome 13 with a defective *GPR180* gene is required to produce the disorder in affected individuals.

Pierson syndrome is caused by a mutation in a different gene, the *LAMB2* gene on chromosome 3 at 3p21.31. The *LAMB2* gene codes for a protein called laminin beta-2, which is an important component of the basement membranes of the glomeruli (clusters of capillaries within the nephrons) in the kidneys, and the smooth muscle cells that

form the inner lining of blood vessels. Unlike MCOR, Pierson syndrome is transmitted in an autosomal recessive pattern, which means that affected persons must receive two copies of the defective gene in order to develop the disorder.

Demographics

MCOR is a rare disease, described in only 50 families worldwide as of 2021. Affected families have been identified in France, Mexico, and Japan, with males and females equally affected. The worldwide incidence of MCOR was unknown as of 2021.

Pierson syndrome is also a rare disease, first identified in a French family in 1963. Other cases have been reported in Turkey, Saudi Arabia, Norway, and the United States. As with MCOR, Pierson syndrome affects males and females equally. In the United States, the only known cases as of 2021 had occurred within Old Order Amish families in eastern Pennsylvania. Genetic counseling and testing for persons from an Amish or Mennonite background is available from the New Leaf Center Clinic for Special Children in Ohio, a program founded on the science of genomics that works to detect and treat inherited health issues.

Signs and symptoms

The signs and symptoms of MCOR include loss of pigmentation, as well as other structural abnormalities in the iris; the absence or underdevelopment of the dilator pupillae muscle; extreme nearsightedness (in 83% of affected individuals) that worsens as the child grows older; glaucoma that manifests as early as age ten and frequently requires treatment; and intraocular pressure (IOP) that is difficult to control with medications. Unlike Pierson syndrome, however, MCOR is not associated with defects in the retina of the eye.

Pierson syndrome is marked by systemic symptoms in addition to congenital microcoria.

- **Neuromuscular symptoms:** Infants with Pierson syndrome typically show delayed motor (movement) development, hypotonia (poor muscle tone, sometimes referred to as “floppy baby syndrome”), some degree of mental retardation, and failure to reach normal developmental milestones.
- **Ocular symptoms:** Like patients with MCOR, infants with Pierson syndrome typically have unusually small pupils that do not dilate normally, together with incomplete development of the iris and an increased risk of glaucoma. Unlike patients with MCOR, however, infants with Pierson syndrome also have an unusually thin retina at the back of the eye, an increased risk of retinal detachment, an increased risk of cataract formation in the lens of the eye, and a lifelong risk of total blindness.

KEY TERMS

Anterior chamber—The fluid-filled front portion of the eye that lies between the iris and the cornea (the transparent front part of the eye that covers the iris and pupil).

Autosomal dominant—A pattern of inheritance in which only one copy of a defective gene on a nonsex chromosome is required for a disease or inherited trait to develop in an individual.

Autosomal recessive—A pattern of inheritance in which two copies of a defective gene on a nonsex chromosome must be present for a disease or inherited trait to develop in an individual.

Autosome—Any human chromosome other than a sex chromosome.

Basement membrane—A thin fibrous noncellular layer of tissue that anchors and separates the epithelium (the skin and the tissue that lines body cavities) from the underlying connective tissue.

Congenital—Present at birth.

Glaucoma—A group of eye disorders resulting in damage to the optic nerve, in most cases as the result of increased intraocular pressure (fluid pressure within the eye). Untreated glaucoma can result in permanent loss of vision.

Glomeruli (singular, glomerulus)—The tiny networks of capillaries in the nephrons (filtering units) of the kidneys that serve to filter the blood during the first stage of urine formation.

Hypotonia—A state of low muscle tone that often involves loss of muscle strength as well. Infants with hypotonia are often described as having “floppy baby syndrome”; they may have difficulty lifting their heads and usually have problems with feeding.

Iris—The thin circular structure in the eye that controls the size of the pupil and thus the amount of light that enters the eye and stimulates the retina. The color of the iris determines an individual’s eye color.

Laminin, beta-2—A protein involved in various biological processes that include cell migration, adhesion, and the formation of basement membranes in the kidneys and the smooth muscle lining of arteries and veins. Mutations in the gene that encode this protein are responsible for Pierson syndrome.

Miosis—The medical term for constriction of the pupil of the eye.

Mydriatics—Medications given to induce dilation of the pupil, usually as part of an eye examination.

Nephrotic syndrome—A kidney disorder caused by damage to the filtering units (glomeruli) of the kidneys and resulting in high levels of protein in the urine, excess fluid in body tissues, and abnormally low blood levels of albumin. It has a variety of genetic and nongenetic causes.

Pierson syndrome—A rare genetic disorder characterized by congenital nephrotic syndrome as well as congenital microcoria. It is named for Michel Pierson, the French physician who first described it in 1963.

Pupil—The circular opening in the iris of the eye that allows light to strike the retina at the back of the eye.

Retina—The light-sensitive layer of tissue at the back of the eye.

Transillumination—A diagnostic technique that involves shining a strong light through body tissues in order to detect defects. Transillumination of the iris may be used to diagnose congenital microcoria.

- **Kidney function:** Patients with Pierson syndrome have a shortened life expectancy due to eventual kidney failure. They have high blood pressure and high levels of protein in the urine. About 90% also have hematuria (blood in the urine).
- **Other:** About 50% of male infants with Pierson syndrome have an underdeveloped penis.

Diagnosis

MCOR may be diagnosed clinically by an ophthalmologist using transillumination of the iris, which usually reveals defects in its tissue structure along with some loss

of color. The pupil of the eye will also be seen to be unusually small and will not dilate when the examiner applies topical mydriatic eye drops. The patient will usually be found to be nearsighted when visual acuity is tested, and the intraocular pressure will often be higher than normal. The clinical diagnosis could potentially be confirmed by genetic testing; however, no genetic testing laboratories were offering tests specifically for MCOR as of 2021.

Pierson syndrome can be diagnosed clinically at birth or shortly afterward by an ophthalmologist or pediatrician on the basis of the abnormalities in the infant’s eyes, hypotonia, slow development of motor (movement)

QUESTIONS TO ASK YOUR DOCTOR

- I am related to the Amish on both sides of my family. What are the chances that I will have a child with Pierson syndrome?
- Should I consider genetic testing for congenital microcoria?
- Would you recommend kidney transplantation for a child with Pierson syndrome?
- Do you think that a genetic test for congenital microcoria will be developed in the near future?

skills, and high blood pressure. Blood and urine tests will show high levels of protein in the urine and low levels of albumin in the blood. The diagnosis can be confirmed by genetic testing. As of 2021, the only laboratory that offered genetic testing specifically for Pierson syndrome was the Institute of Human Genetics in Cologne, Germany. The test performed is sequence analysis of the entire coding region of the *LAMB2* gene.

Treatment and management

MCOR can be managed by regular eye examinations that include careful monitoring of intraocular pressure as well as changes in visual acuity. Because the intraocular pressure in patients with MCOR does not respond to medications, surgery is necessary to treat glaucoma.

There is no cure for Pierson syndrome. Life expectancy varies according to the time of the onset of kidney failure, with death in infancy or early childhood commonplace. Lifelong monitoring by a kidney specialist is essential. While a kidney transplant may extend the patient's life, the severe neuromuscular and intellectual impairments characteristic of the syndrome may not justify the complications that often accompany organ transplantation. Retinal detachment, cataracts, and glaucoma can be treated surgically in selected patients.

Prognosis

Patients with MCOR have a normal life expectancy, although their nearsightedness typically worsens as they age, and they have a lifelong increased risk of glaucoma.

The prognosis of Pierson syndrome is poor, with slow motor development and hypotonia complicating the patient's defects in vision and kidney function. Individuals who survive past infancy typically do not reach such normal developmental milestones as sitting, standing, and walking.

Rebecca J. Frey, PhD

Conjoined twins

Definition

Conjoined twins are an extremely rare type of identical twins who are born physically joined.

Description

Scientists believe that conjoined twins form because of a delay in the division of an early embryo to form identical twins. With normal identical twins, the embryo starts to divide within the first 12 days to form two separate embryos. In conjoined twins, however, the split occurs

An x-ray image of conjoined twins. (Biophoto Associates/Science Source)

sometime after day 12. Instead of forming two separate embryos, the twins remain partially attached as they develop inside the womb. There are two theories of why this happens. The fission theory proposes that if the division starts after day 12, the embryos never fully separate, resulting in conjoined twins. The fusion theory proposes that two initially separate identical twins rejoin for unknown reasons.

In most cases, conjoined twins do not survive more than a few days past birth because of malformed organs and other severe birth abnormalities. However, surgery often can separate surviving conjoined twins. The phrase “Siamese twins,” which is now considered derogatory, originated with the famous conjoined twins Eng and Chang Bunker, who were born in Siam (Thailand) in 1811.

Conjoined twins may be connected at virtually any point of their bodies, but they are most often connected at the chest, pelvis, or buttocks. They may share one or more internal organs, such as a heart, liver, or brain. Conjoined twins are classified according to where they are joined.

Upper body

- Cephalopagus is a rare form of fused upper bodies and two faces on opposite sides of a single head.

- Craniopagus—conjoined twins with separate bodies and one shared head—occurs in only 2% of cases.
- Thoracopagus occurs in about 35% of conjoined twin births. These twins usually share a heart, making surgical separation nearly impossible.

Lower body

- Ischiopagus—attachment at the lower half of the body—occurs in about 6% of conjoined twins.
- Omphalopagus, in which conjoined twins are attached at the abdomen and often share a liver, accounts for approximately 30% of all cases.
- Parapagus—attachment along the side of the lower bodies—accounts for about 5% of conjoined twins.
- Pygopagus—joined back-to-back with fused buttocks—accounts for about 19% of conjoined twins.

Rare types

- Dicephalus are twins who share one body but have two separate heads and necks.
- Parasitic twins include one smaller malformed twin who is dependent on the larger, stronger twin for survival.

- Fetus in fetu is an unusual case in which one fetus grows inside the body of the other twin.

Genetic profile

The cause of conjoined twins is unknown. It is believed that a combination of genetic and environmental factors may be responsible for this rare condition.

Demographics

Conjoined twins occur in one out of every 50,000 births. Many such pregnancies are terminated before

Skeleton of conjoined twins showing that each had its own head, neck, and trachea, but shared the rest of the body. The medical name for this condition is dicephalus dibrachius, and most afflicted infants are stillborn or die soon after birth. As with identical twins, conjoined twins result from the fertilization of a single egg cell, but in these cases the spitting of the embryo into two identical bodies is incomplete. (Arno Massee/Science Source)

KEY TERMS

Breech delivery—Birth of an infant feet- or buttocks-first.

Craniopagus—Conjoined twins with separate bodies and one shared head.

Dicephalus—Conjoined twins who share one body but have two separate heads and necks.

Fetus in fetu—A fetus growing inside the body of the other twin.

Ischiopagus—Conjoined twins who are attached at the lower half of the body.

Omphalopagus—Conjoined twins who are attached at the abdomen.

Parapagus—Conjoined twins who are joined at the side of their lower bodies.

Parasitic twins—Twins who include a smaller, malformed twin who is dependent on the larger, stronger twin for survival.

Pygopagus—Conjoined twins who are joined back-to-back with fused buttocks.

Thoracopagus—Conjoined twins joined at the upper body who share a heart.

birth, or the infants are stillborn. Conjoined twins are always identical and of the same sex. They are more often female than male, by a ratio of three to one. Conjoined twins are more common in Africa, India, China, and Latin America than in the United States or Europe. Conjoined twins have occurred as part of a triplet or quadruplet pregnancy but not as one single conjoined group of more than two. Most parents of conjoined twins are younger than age 35.

Signs and symptoms

Approximately 50% of women who are pregnant with conjoined twins will develop excess fluid surrounding the fetuses, which can lead to premature labor and an increased risk of miscarriage. Conjoined twins joined at the abdomen (omphalopagus) are more likely to be a breech presentation at delivery. In breech births, infants are born feet- or buttocks-first instead of head-first. However, most conjoined twins are born by cesarean delivery to increase their odds of survival.

Conjoined twins can be born with a complication called hydrops, which causes excessive fluid to build up in the infant's body and can be life-threatening. Those who survive past birth may experience congenital heart disease, liver or kidney disease, physical or mental disabilities, and/or intestinal blockages.

QUESTIONS TO ASK YOUR DOCTOR

- What is the process by which conjoined twins are formed?
- Are there ways to prevent the formation of conjoined twins?
- On what factors does the success of surgical separation of conjoined twins depend?
- What is the prognosis for conjoined twins who are surgically separated after birth?
- What is the risk of having conjoined twins in a subsequent pregnancy?

Diagnosis

Physicians usually diagnose conjoined twins early in pregnancy through ultrasound, a technique in which high-frequency sound waves create a picture of a developing fetus inside the uterus. Initial diagnosis is possible at 10–12 weeks of gestation, but it is difficult to determine which body structures are involved until 20 weeks of gestation. Before ten weeks of gestation, identical twins who share an amniotic sac may appear to be conjoined. Halfway through the pregnancy, more detailed ultrasounds and echocardiograms can be used to determine the connection and the sharing and functioning of organs.

Treatment and management

Early diagnosis is key so that families and healthcare providers can plan for the birth of conjoined twins or end the pregnancy. Because of the high rate of miscarriage and difficult labor, most conjoined twins are delivered by cesarean delivery. Some conjoined twins have survived and lived full lives without serious medical interventions. If the twins do not share a large number of organs, however, physicians typically recommend a surgical separation.

A large medical team must be assembled for a surgical separation. Physicians prefer to wait for a few months after birth before attempting surgical separation, but that may not be possible if the twins are born with life-threatening abnormalities. An emergency surgical separation may be required if one twin dies, develops a life-threatening condition, or otherwise threatens the survival of the other twin. The type of surgery that is performed is determined by where the twins are connected. Doctors will often insert tissue-expansion devices into the twins' skin before the operation to promote better healing at the site of separation.

Conjoined twins who survive a surgical separation will have many ongoing healthcare needs, from wound care to reconstructive surgeries, prosthetic limbs, and special diets. As the twins grow up and start school, they may need counseling to help them adjust.

Prognosis

About 40%–60% of conjoined twins are stillborn. Of those born alive, fewer than half survive long enough for separation surgery. The prognosis for separation surgery depends on where the twins are joined and what organs are shared. However, advances in prenatal imaging and critical care have improved separation surgery outcomes.

In 2011, 11-month-old Sudanese twins joined at the head were successfully separated in a series of four surgeries. In 2020, a set of Californian twins conjoined at the head were successfully separated after 24 hours of surgery by 30 surgical health providers. They were separated at nine months of age in the midst of the Covid-19 pandemic. The twins were diagnosed at 11 weeks of gestation. Before birth, doctors created doll replicas of the twins. That helped the team plan how to deliver the babies. After birth, in preparation for the surgery, the doctors placed tissue expanders underneath the babies' skin so that more skin would grow. That was necessary so that there would be enough skin to cover the skulls of both girls after surgery. The surgeons also used 3D printing of models of the twins' skulls to prepare for surgery.

Other conjoined twins have lived successful lives without being separated. For example, Abby and Brittany Hensel were born in 1990. Their parents decided not to separate them because of the risk that one of the girls would die. The twins share their body from their pelvis down and each twin controls one side of their body. It was a challenge for them to learn how to coordinate their movements. They even each have a driver's license. They have different personalities and hobbies. In 2021, thirty-one years later, they are still doing well. Both are teachers, but Abby studied and teaches math, while Brittany studied and teaches English. They hope to each marry a different man and have children. Although they prefer privacy now, they had their own reality TV show in 2012.

Connectome genetics

Definition

The connectome is a comprehensive map of all the neural connections in the brain. Much like a blueprint or a schematic, a connectome includes the mapping of all neural connections within an organism's nervous system.

Connectome genetics is the scientific attempt to discover and record how genetic factors affect the neural connections of the brain. The term "connectome" was coined by Dr. Olaf Sporns and Dr. Patric Hagmann in 2005 to describe a literal map of the entirety of the neurological connections of the brain. Connectome genetics applies the methods of genetic research to the concept of neural mapping to determine the genetic factors involved.

Description

Researchers study the genetics of the connectome in an attempt to identify the ways that different regions of the brain are connected and work cooperatively as one integrated system to accomplish the various functions of the brain such as emotion, thought, and activity, and how that system is influenced by genetics. The regions of the brain are organized into parallel systems that interact and are physically connected. The human connectome seeks to provide methods and mapping so that connectivity may be measured and its influence understood. Discovering the genetic factors involved in this connectivity will determine the inherited aspects of neural connection, and help identify abnormal development and the origins of degenerative processes.

While it is not currently possible to assess the entire human connectome and all genetic influences, significant discoveries may be made by employing multiple research methods. In order to understand the genetic influences of neural connections on a scale as large as the human connectome, multiple scientific research tools have been employed. Researchers have compared results from genetic analysis methods such as genome-wide association studies (GWAS); linkage and candidate gene studies; neural imaging tests such as resting state and functional magnetic resonance imaging (fMRI and R-fMRI); and groups working to compile large databases with information of genetic inheritance, such as the Evidence-Based Network for the Interpretation of Germline Mutant Alleles (ENIGMA), to understand the genetics of the connectome on an individual or group level.

According to the National Human Genome Research Institute, GWAS is an approach that involves rapidly scanning markers across the complete sets of DNA, or genomes, of many people to find genetic variations associated with a particular disease. Once new genetic associations are identified, researchers can use the information to develop better strategies to detect, treat, and prevent the disease. This methodology was made possible by the Human Genome Project and the tools it provided researchers around the world such as large databases of the reference human genome sequence, a map of human genetic variation, and innovative new technologies that

allow the quick and accurate analysis of entire genome samples.

Linkage and candidate gene studies use a single gene approach rather than the entire genome approach used in GWAS. After a candidate gene (a gene believed to be responsible for causing a specific condition or disease) is selected, that gene is compared to the same gene from another individual with the same condition and to genes from other individuals who do not have the condition to determine whether the candidate gene is responsible.

Imaging studies are especially useful in connectome research because they provide a detailed image of neural connections. Two types of MRI used in connectome and genetic research are resting state functional connectivity MRI (fcMRI) and high angular resolution diffusion imaging (HARDI).

An fcMRI is often used to investigate networks in the brain, especially those that demonstrate correlated fluctuations. Even though this test does not offer the ability to provide direct measurement of anatomic connectivity, research data suggests that the neural anatomy seen in fcMRI images shows enough distinct brain system architecture to be useful in drawing conclusions. It is particularly useful for characterizing large-scale systems that span widespread areas such as polysynaptic cortical pathways, cerebro-cerebellar circuits, and cortical-thalamic circuits.

HARDI is another MRI technique used to help identify the genetics of the connectome. This technique uses the distribution of water molecules in tissue to map fiber tracts inside the brain. HARDI is preferred over another more common technique called diffusion tensor imaging (DTI) because HARDI is able to image fiber tracts that cross, fan out, or become intertwined as many neural pathways do.

The advantage of both fcMRI and HARDI is that they are noninvasive ways to map the human brain. Previously, mapping was conducted after death by actual physical examination and dissection of the brain, or by using invasive tracing methods that required a tissue sample from the brain. HARDI and fcMRI technologies cause little discomfort to the patient and provide a much richer body of data.

The ENIGMA Consortium was established in order to analyze brain measures and genotypes from multiple sites across the world. This analysis is designed to improve the power to detect genetic variants that influence the brain. One ENIGMA working group analyzed high-resolution DCI images from multiple imaging sites across North America, Australia, and Europe to address the challenge of combining imaging data collected from multiple sites.

This research has already uncovered how some diseases and genetic mutations affect the brain. Researchers

KEY TERMS

Allele—One member of a pair of genes.

Amnesic mild cognitive impairment (aMCI)—An early symptom of Alzheimer's disease in which there is mild impairment but normal cognitive functioning is still present.

Biomarker—A measurable indicator of a biological function.

Cerebro-cerebellar circuits—Neural pathways that originate in the cerebral cortex and travel through the deeper structures of the brain and back to the cerebral cortex. They control verbal working memory and other higher-order brain functions.

Cortical-thalamic circuits—A circular connection within the brain that travels between the cerebral cortex and the thalamus and back to the cerebral cortex. Scientists believe it helps the brain monitor its status.

Genetic locus (plural, loci)—The specific location of a gene on a chromosome.

Genome—An organism's complete set of DNA.

Polysynaptic cortical pathways—The pathway by which stimuli enter the brain.

have also identified new genetic loci and interrelated genetic networks that influence and control neural networks within the brain.

Genetic profile

In order to analyze the significance of genetic contributions to the human connectome, quantitative classical genetics techniques may be employed to determine which trait variance may be attributed to genetic factors, which are attributable to environmental factors, which are epistatic (a result of the influence of one gene on another), and which are due to the interaction between environment and inheritance. The proportion of trait variance within a population that is due to genetic factors is the heritability of that trait. Calculating heritability estimates is a valuable exercise for novel traits that have been identified using complex image analyses such as the connectome. These methods are particularly helpful in efforts to discover genetic variants affecting brain measures because they can help identify traits that are more likely to be inherited or passed on to offspring. Once these traits are identified, researchers can use valuable resources to perform genetic analysis on the heritable traits.

Demographics

The connectome project is ongoing. In 2015, the demographics of the genetics of the connectome had not been determined.

Signs and symptoms

An important component of the Human Connectome Project is discovering clinical applications for connectomics (the science of the connectome). One important functional discovery is the function and validity of biomarkers. Biomarkers (biological markers) are a biological measure of a biological state. Using R-fMRI, a type of fcMRI, variations in the functional connectome may be identified and combined with known genetic factors; these variations can be connected to clinical or diagnostic features of diseases and condition of the brain. For example, Alzheimer's disease currently affects 2.4 million to 4.5 million in the United States alone. Researchers have discovered that mutations in the *APP*, *PSEN1*, or *PSEN2* genes cause Alzheimer's disease. In 2013, using fcMRI and functional connectome methodologies, researchers discovered that even in amnesic mild cognitive impairment (aMCI), the earliest stage of Alzheimer's disease, there is evidence that the entire connectome is disrupted. This finding may be helpful for diagnostic purposes in this population and for use as a biomarker.

There are still many challenges to the routine use of the connectome and biomarker identification for diagnostic purposes. By applying clinical test evaluation measures such as validity, reliability, sensitivity, specificity, and applicability, researchers hope to expand these prospects to include risk assessment, treatment response, and prognosis prediction.

Diagnosis

The genetics of the connectome are particularly relevant for the field of psychiatry. Disorders that affect behavior and mental functioning may be attributed to specific identifiable abnormalities in the very neural pathways and connections that the connection will map.

There are many psychiatric conditions caused by interruptions in the human connectome. In particular, schizophrenia has been shown to be a condition caused by interruptions of the neural connections and pathways of the brain. The human connectome project has identified areas of interest related to schizophrenia. Using the imaging technologies of structural, diffusion, resting-state, and task-related functional imaging, and advanced computational analysis methods such as graph theory, more than 200 publications have addressed different aspects of structural and/or functional connectivity in schizophrenia in 2015 alone. This research and the

discoveries made help identify the genetic components of the connectome as it relates to schizophrenia. More than 45 different single-gene mutations have been associated with an increased risk of developing schizophrenia. Research in the connectome may lead to the identification of how each of these genes affects neural pathways in the brain and improved diagnosis and treatment.

Many more discoveries may be expected related to the genetics of the connectome. Eventually, the results of the connectome will help diagnose multiple conditions and diseases that affect the brain.

Treatment and management

There are currently no treatment options for diseases using the genetics of the connectome. Researchers are investigating the connectome as a tool to identify biomarkers for psychiatric and neurological conditions and diseases. In the course of this research, it is expected that treatment options may be discovered as well.

Prognosis

Using the science of connectomics, researchers are attempting to use R-fMRI and the connectome to improve the prognosis of patients with psychiatric disorders such as schizophrenia and conditions of brain deterioration such as Alzheimer's disease. They have had success identifying biomarkers useful for diagnosis and for identifying disease progression. These discoveries have led them to believe prognosis prediction may be possible using the same methodologies.

Corneal dystrophy

Definition

Corneal dystrophy is a condition that causes a layer of the cornea to cloud over and impair visual clarity. It is usually a bilateral problem, which means it occurs in both eyes equally. There are more than 20 different forms of inherited corneal dystrophies. A corneal dystrophy can occur in otherwise healthy individuals. Depending on the type of condition and the age of the individual, a corneal dystrophy may cause no problems, moderate vision impairment, or severe difficulties that require surgery.

Description

The cornea is the outside layer of the eye, and is comprised of five layers, including the outer epithelium; the Bowman's layer; the stroma, or middle layer that takes up about 90% of the entire cornea; Descemet's membrane; and the endothelium. In most cases, the central (stromal) layer of the cornea is involved.

Some corneal dystrophies are named after the individual who discovered them, while others are descriptive of the pattern seen with the dystrophy or the location of the disease. The key forms of corneal dystrophy are congenital hereditary endothelial dystrophy (CHED), epithelial basement membrane dystrophy ("map-dot-fingerprint" dystrophy), Fuchs' endothelial dystrophy, granular dystrophy, lattice dystrophy, macular corneal dystrophy, Meesmann's corneal dystrophy, posterior polymorphous dystrophy (PPD), and Reis-Bücklers' dystrophy.

According to the International Committee for Classification of Corneal Diseases (IC3D), corneal dystrophies are classified by the anatomic layer of corneal involvement, but they are increasingly defined on a genetic basis.

Genetic profile

As of 2021, some 293 genetic alterations (mutations) causing corneal dystrophies had been mapped to 18 different genes that include *COL8A2*, *TGFBI*, *VSX1*, *CHST6*, *KRT3*, *KRT12*, *GSN*, *TACSTD2*, *CYP4V2*, *SOD1*, *TCF8/ZEB1*, *UBIAD1*, *PIKFYVE*, *DCN*, and *SLC4A11*. Genetic variations in these genes have been associated with several corneal dystrophies, which are linked to epithelium, stroma, and endothelium.

Some corneal dystrophies have the same genetic address. Mutations on the *BIGH3* gene on chromosome 5q31 cause granular corneal dystrophy and Reis-Bücklers' dystrophy. Macular corneal dystrophy has been mapped to an altered gene on chromosome 16. The mutation causing congenital hereditary endothelial dystrophy

KEY TERMS

Basement membrane—Part of the epithelium, or outer layer of the cornea.

Bowman's layer—Transparent sheet of tissue directly below the basement membrane.

Corneal transplant—Removal of impaired and diseased cornea and replacement with corneal tissue from a recently deceased person.

Descemet's membrane—Sheet of tissue that lies under the stroma and protects against infection and injuries.

Edema—Extreme amount of watery fluid that causes swelling of the affected tissue.

Endothelium—Extremely thin innermost layer of the cornea.

Epithelium—The layer of cells that cover the open surfaces of the body such as the skin and mucous membranes.

Hyaline—A clear substance that occurs in cell deterioration.

Stroma—Middle layer of the cornea, representing about 90% of the entire cornea.

has been mapped to 20p11-20q11. Lattice type I is linked to the 5q31 locus (location), while lattice type II dystrophy is linked to the 9q34 locus. Posterior polymorphous corneal dystrophy has been linked to the 20q11 locus.

Most corneal dystrophies, with the exception of congenital endothelial corneal dystrophy and macular dystrophy, are autosomal dominant. In dominant disorders, a single copy of the mutated gene (received from either parent) dominates the normal gene and results in the appearance of the disease. The risk of transmitting the disorder from parent to offspring is 50% for each pregnancy.

Both congenital endothelial corneal dystrophy and macular dystrophy are autosomal recessive. This means the affected person inherits the same abnormal gene for the same trait from both parents; each parent is a carrier for the disease but usually does not have symptoms of the disease. The risk of transmitting the disease to each pregnancy is 25%.

Demographics

The diversity of corneal dystrophy diseases makes it difficult to provide specific demographic data. Some dystrophies appear in early childhood or even infancy, such as Reis-Bücklers' dystrophy. Others may not appear until

middle age or beyond, as with Fuchs' dystrophy. It generally begins at 30–40 years of age and gradually progresses, affecting women slightly more than men. Epithelial basement membrane dystrophy generally occurs in adults after the age of 40, and it can come as late as age 70.

Signs and symptoms

The symptoms vary with the type of corneal dystrophy and the location of the site. Most experts categorize these diseases based on whether they are located on the anterior (outer) layer, stromal (middle) layer, or endothelial (inner) layer.

Anterior corneal dystrophies

The epithelium, or the basement membrane, and the Bowman's layer together comprise the anterior, or outer part, of the cornea. Epithelial basement membrane dystrophy, also known as Cogan's map-dot-fingerprint dystrophy, is a disorder that causes errors in refractions of the eye and may also present with microscopic cysts. This disease results from excessive fluid (edema) and swelling of the basement membrane into the epithelium. Symptoms of this disease are map-like dots, opaque circles, or thin lines that are formed in a swirled pattern like fingerprints. Individuals with this disorder feel like they have something irritating in the eye and experience pain and light sensitivity (photophobia).

The tiny opaque collagen fibers that cause Reis-Bücklers' dystrophy create a linear or ring-like pattern. People with this disease have recurrent painful erosions of the cornea and may also suffer from severe visual impairment. Reis-Bücklers' is usually noticed in an infant or young child who suddenly has very red eyes. To the ophthalmologist, the cornea looks like frosted glass. This disorder may recur several times per year and disappear when affected individuals are in their 20s or 30s.

Stromal dystrophies

The primary dystrophies found in the stromal layer are granular dystrophy, lattice dystrophy, and macular dystrophy. Granular dystrophy is so named because of the small opaque areas caused by deposits of hyaline, a substance that accumulates as cells deteriorate. Lattice dystrophy is caused by deposits of amyloid, the same substance that accumulates in the brain in people with Alzheimer's disease. Both granular dystrophy and lattice dystrophy have been identified in family members in Avellino, Italy, and these dystrophies are sometimes grouped together and called Avellino corneal dystrophy. Lattice and granular dystrophies can cause severe eye pain. With lattice dystrophy, by about age 40, an affected

QUESTIONS TO ASK YOUR DOCTOR

- My partner has corneal dystrophy. Is he or she a candidate for a corneal transplant?
- What changes in vision can I expect as a result of a corneal transplant?
- Are there symptoms that we should watch for in assessing the ongoing status of corneal dystrophy?
- I have diabetes and hypertension in addition to corneal dystrophy. Will other medical conditions such as these affect my condition?

person's vision can be very obscured and a corneal transplant is required.

Endothelial dystrophies

Fuchs' dystrophy is the most common of the endothelial dystrophies and is inherited as an autosomal dominant trait. It is characterized by blurred vision, hypersensitivity to light (photophobia), and two to eight acute inflammatory attacks per year. It may also cause ulceration and erosion of the cornea. Fuchs' can cause deterioration of endothelial cells and result in corneal guttata, which are thickenings or leakages from the Descemet's membrane of the cornea. These guttata eventually cause edema (excessive fluid) to leak into the stromal or epithelial areas.

Posterior polymorphous dystrophy (PPD), an autosomal dominant disease, also causes edema, although it affects a larger area than Fuchs' dystrophy. It usually does not cause vision impairment.

Congenital hereditary endothelial dystrophy (CHED) comprises two types. The autosomal dominant form is CHED 1, and the recessive form is CHED 2. CHED 1 can occur in early childhood and may also cause hearing loss. The key symptoms of CHED 1 are sensitivity to light and excessive tearing. CHED 2 is present at birth and is more severe than CHED 1. In both CHED 1 and 2, the cornea presents with a milky haze or the appearance of ground glass.

Macular dystrophy is inherited as an autosomal recessive trait. It can present as early as age three, and up to about age nine, and is very debilitating. This disorder is caused by deposits of keratin sulfate (sulfur-containing fibrous proteins) and becomes increasingly painful. The child will have a feeling of something in

the eye and also experience photophobia (sensitivity to light).

Diagnosis

Corneal dystrophy may be identified by an optometrist and diagnosed by an ophthalmologist. The findings determine the existence and type of corneal dystrophy. The presence, size, and shape of any opaque material in the eyes are considered.

The affected cornea of a person with lattice dystrophy will have a ground-glass appearance, while granular deposits indicate granular dystrophy. The examination can also reveal the presence of amyloid deposits, which are typical of individuals with lattice dystrophy.

Treatment and management

Treatment depends on the severity of the disease. If the affected person is in acute pain, treatment with eye drops, antibiotics, and other solutions is necessary. Some doctors advise affected people with eye edema to use a hair dryer at arm's length to dry some of the edema. Soft contact lenses may also help. Individuals with increasingly severe vision problems may need a corneal transplant.

For other forms of corneal dystrophy, affected people may need artificial tears and other medications. Some individuals may need laser treatment, such as phototherapeutic keratectomy (PK), which is the removal of part of the corneal stroma, or they may need a corneal transplant. Endothelial keratoplasty, a cornea-sparing transplant technique that replaces only the diseased endothelial cell layer of the patient's cornea, may also be recommended by an ophthalmologist.

Clinical trials

Clinical trials on corneal dystrophies are currently sponsored by the National Institutes of Health (NIH) and other agencies. In 2021, NIH reported 95 ongoing or active studies.

Clinical trial information is constantly updated by NIH and the most recent information on corneal dystrophy trials can be found at: <http://clinicaltrials.gov/ct2/results?term=corneal+dystrophy>.

Prognosis

With most forms of corneal dystrophy, the disease progresses as the affected person ages. The severity of the conditions varies and a particular form of the disease may cause few or no problems or may also cause severe visual difficulties requiring surgery. Cases must be evaluated individually.

Cornelia de Lange syndrome

Definition

Cornelia de Lange syndrome (CdLS) is a genetic disorder characterized by multiple birth defects, including

distinctive facial features, prenatal and postnatal growth delays, feeding difficulties, psychomotor delay, behavioral problems, and associated malformations that primarily involve the upper extremities. CdLS is caused by mutations in genes that are important for prenatal and postnatal development.

Description

CdLS is named for Cornelia de Lange, the Dutch physician who first described it as a distinct syndrome in 1933. It is sometimes called Brachmann-de Lange syndrome, after W. Brachmann, who described a severe form of the syndrome in 1916.

Three distinct forms of CdLS are recognized. Type I is the most severe or “classic” form. Children with this type have a prenatal growth deficiency that continues after birth. They have distinctive facial features and moderate-to-profound mental retardation. Major deformities of the gastrointestinal tract and heart may lead to severe disability or death. Type II is the mild form of CdLS. Facial features are similar to those of Type I but may not become apparent until later in life. Pre- and postnatal growth deficiencies are less severe, and major malformations are less likely. Type III CdLS, called a phenocopy, includes patients with characteristics of CdLS that are caused by chromosomal aneuploidies (an abnormal number of chromosomes) or teratogenic (birth-defect-inducing) factors.

Genetic profile

CdLS can be caused by mutations (changes) in a gene called *NIPBL*, located on chromosome 5. Although the exact function of the protein produced by *NIPBL* (known as delangin in humans) is unknown, the corresponding proteins in other species are involved in the regulation of development and in the joining of sister chromatids during chromosome duplication prior to cell division. More than half of patients with CdLS appear to have mutations in the *NIPBL* gene. Many different mutations in *NIPBL* have been reported to result in CdLS, although the severity of the syndrome varies, depending on the specific mutation.

Mutations in four other genes—*SMC1A*, *SMC3*, *HDAC8*, and *RAD21*—have been identified as resulting in CdLS. Mutations in *SMC1A* and *SMC3* have been reported in 5% and 1% of patients with CdLS respectively. Like *NIPBL*, *SMC1A* and *SMC3* produce proteins that are involved in the cohesion of sister chromatids. Thus, CdLS is considered to be a “cohesinopathy,” in which the separation of sister chromatids during cell division is disrupted, resulting in daughter cells that may lack one chromosome of a chromosome pair, a condition

A young male patient with Cornelia de Lange syndrome. This genetic disorder affects both the physical and mental development of a child, with features such as widely spaced teeth, autistic-like behaviors, and excessive hairiness. (SPL/Science Source)

known as haploinsufficiency. These proteins are important for the structure and organization of chromosomes. They are also involved in repairing damaged DNA and in regulating other genes that direct the development of the limbs, face, and other body parts. Mutations in *SMC1A* and *SMC3* cause milder forms of CdLS than mutations in *NIPBL* do. Severe limb defects and other structural anomalies are absent. In some patients with these gene mutations, mental retardation is the only obvious symptom.

It is believed that other genes may also be involved in CdLS, since in about 35% of cases, the cause has not been identified. The fact that CdLS can be caused by mutations in several different genes probably helps explain the variability in signs and symptoms of CdLS.

NIPBL and *SMC3* gene mutations can be inherited in an autosomal dominant pattern, meaning that only one copy of the mutated gene is sufficient to cause CdLS, even when the second copy of the gene is normal. *SMC1A* gene mutations are inherited as X-linked

dominants, which means that the gene is located on the X sex chromosome, and mutations cause CdLS even when a second copy of the gene on the other X chromosome in females is normal. (Males have only one X chromosome, inherited from their mother.) In a few known cases of inherited CdLS, a parent was mildly affected by the syndrome. However, more than 99% of CdLS cases are sporadic—resulting from new, spontaneous mutations in the egg or sperm or during fetal development—rather than inherited from a parent.

Demographics

CdLS is estimated to affect one in 10,000 newborns. It appears to affect males and females of all races equally.

Signs and symptoms

Musculoskeletal abnormalities

Most newborns with CdLS have low birth weight, cleft palate, and a low-pitched growl or cry. Characteristic facial features include thin eyebrows joined at the midline (known as synophrys), long eyelashes, excessive facial and body hair (hypertrichosis), and thin, downturned lips. In mild cases, this classic appearance might not be present at birth, and it might not become obvious for two or three years. CdLS can also result in:

- microcephaly—an abnormally small head accompanied by a small brain, resulting in mild-to-profound mental retardation
- micrognathia—an abnormally small mandible or lower jaw bone
- a small nose
- anteversion, or turning, of the nostrils
- a long philtrum (the area between the nose and upper lip)
- relatively short limbs
- limitations of elbow extension in mild forms
- small hands and/or feet
- oligodactyly—fewer than five digits on the hands or feet
- clinodactyly, or bending of the fifth finger and thumb
- webbing of the toes (syndactyly)

Gastrointestinal abnormalities

The upper and lower gastrointestinal (GI) tract is the body system most commonly affected by CdLS:

- Gastroesophageal reflux disease (GERD) is caused by acid from the stomach refluxing back into the esophagus, which can lead to severe heartburn and, if left untreated, can damage the esophagus (reflux esophagitis) due to

repeated irritation. Gastroesophageal reflux can also cause symptoms of pulmonary congestion and irritation due to chemical pneumonitis (inflammation of the lung).

- Barrett's esophagus is a change in the tissue type of the lower esophagus. It is usually a complication of GERD and may develop into an adenocarcinoma (carcinoma of glandular tissue).
- Esophageal stenosis is a narrowing of the esophagus, which may decrease esophageal motility and make feeding difficult.
- Gastric ulcers are usually caused by bacteria and can lead to abdominal discomfort.
- Pyloric stenosis is a narrowing of the pyloric canal that leads from the stomach to the duodenum. It may result in vomiting and diarrhea complicated by electrolyte imbalances.
- Intestinal malrotation is a failure of the normal rotation of the small intestine during fetal development. It can cause a volvulus—a twisting of the intestine back on itself—cutting off blood supply to the tissue or possibly causing intestinal obstruction.
- Meckel diverticula are tiny pouches that protrude into the small intestine. Sometimes ulceration develops, and bleeding occurs.

Cardiac abnormalities

Heart problems are not uncommon in patients with CdLS.

- Ventricular septal defect is a condition in which the septum of the ventricles (the wall between the lower chambers of the heart) is not fully closed, resulting in a

Syndactyly (fusion) of the toes in a young male patient with Cornelia de Lange syndrome. This syndrome is a genetic disorder that affects both the physical and mental development of a child. (SPL/Science Source)

heart murmur. It can possibly lead to congestive heart failure.

- Infective endocarditis is an infection of the endothelium, the tissue that lines the heart.
- Atrial septal defect is a defect of the septum between the upper chambers of the heart. It is caused by the persistence of the foramen ovale, which is a hole normally present in the fetal heart that closes at birth. Individuals with this condition may also have a heart murmur. Symptoms are normally not present in patients with atrial septal defects, but there is an increased risk of infective endocarditis.
- Patent ductus arteriosus is a failure of the ductus arteriosus—a blood vessel between the pulmonary artery and the aorta found only in the fetus—to close. Severe cases may require surgery.
- Pulmonary valve stenosis is a narrowing of the valve that allows blood to move from the right ventricle to the lungs. It may result in right-sided heart enlargement and heart failure.
- Tetralogy of Fallot is a condition consisting of pulmonary stenosis, ventricular septal defect, enlarged right ventricle, and a displaced aorta. This condition results in a decrease in oxygenated blood pumped to the body. It can normally be corrected by surgery.

Growth and developmental deficiencies

Most infants afflicted with CdLS have both prenatal and postnatal growth deficiencies as well as developmental delays, which may be due to endocrine system involvement, including growth hormone delivery problems. Most CdLS patients have a characteristically short stature but often have a pubertal growth spurt at a comparable age to normal teens.

Developmental delays are numerous and affect most patients with CdLS. They can include walking, speaking, toilet training, and dressing. Some children never reach these milestones. The average IQ is 53—within the mild-to-moderate range for mental retardation.

Disorders of ears and eyes

Many patients with CdLS have some form of hearing loss, ranging from mild to severe and affecting one or both ears. This loss can be attributed to a lack of prenatal development of some of the important bony structures associated with the inner ear. Developmental failure of important neural elements also plays a role in hearing loss.

A significant number of CdLS patients have eye and/or vision problems including:

- myopia—nearsightedness or shortsightedness
- nystagmus—rhythmical oscillations of the eyes slowly to one side followed by a rapid reflex movement in the

opposite direction—usually horizontal, although rotatory or vertical nystagmus also occur

- ptosis, or drooping eyelid(s), possibly resulting from lesions in either the brainstem or the nerves supplying the muscles that raise the eyelid
- nasolacrimal duct fistula that prevents tears from draining from the eyeball, which may develop into chronic tearing and discharge from the eyes

Dysfunctional placenta

Researchers have demonstrated that a dysfunctional placenta can play a formerly unknown role during the earliest phases of development in mouse models of CdLS. People with CdLS often harbor mutations in cohesins, ring-like proteins that help DNA organize and repair itself. Mice with cohesin mutations had placentas that built up damage to their DNA, assumed a permanent growth-arrested state called senescence, and released pro-inflammatory cytokines that impacted the growth of the embryos. Targeting cytokine signaling could offer a way to safeguard the health of the placenta and support healthy pregnancies.

Other symptoms

Other malformations include undescended testicles, which can cause fertility problems. Diaphragmatic hernia is a complication that may lead to GI difficulties. CdLS patients may also have seizures, feeding difficulties, and behavioral and communication problems.

Diagnosis

CdLS diagnosis is based on signs and symptoms, which are often apparent at birth; however, the syndrome varies considerably. Characteristic facial features may be the most prominent diagnostic clues. Prenatal diagnosis is possible through the use of ultrasound. The association of intrauterine growth retardation, oligodactyly, an absent ulna (one of the two long bones of the forearm), underdevelopment of hands, diaphragmatic hernia, and cardiac defects leads to the differential diagnosis. The most distinctive abnormalities are those of the upper limbs. Researchers have also found that maternal serum samples collected from women who gave birth to a child with CdLS had low levels of pregnancy-associated plasma protein-A (PAPP-A) during the second trimester. In addition, it has been noted that an amniotic molecule (5-OH-indole-3-acetic acid) and a fetal serum protein (galactose-1-phosphate-uridylyltransferase) are increased prenatally. Genetic testing for relevant gene mutations can be diagnostic, but many patients with CdLS test negative for the known mutations.

Treatment and management

The treatment and management of patients with CdLS are strictly symptomatic. Treatment is prescribed according to presenting symptoms. However, treatment and management are usually complex and lifelong, requiring the involvement of numerous specialists.

Musculoskeletal concerns

For patients with limb and digit malformations, a variety of prostheses may be necessary. Physical and occupational therapy may also be needed. Surgery may be necessary to correct more severe deformities.

Gastrointestinal treatment

GERD can be treated with special diets and a number of different drugs that either block acid secretion from the stomach or neutralize acid once it is produced. Drugs may include antacids, histamine receptor blockers, and proton pump inhibitors. If these treatments prove unsuccessful, surgery may be performed to eliminate the possibility of further complications such as Barrett's esophagus or esophageal stenosis. Patients with CdLS should have endoscopic evaluation with biopsies for Barrett's esophagus. If Barrett's esophagus occurs, treatment will include the aforementioned drugs to reduce stomach acid, and removal of the precancerous tissue may be indicated. Surgery to shorten the esophagus may also be performed. Esophageal stenosis treatment may include a procedure for dilating the esophagus. Some patients may require surgery to implant a stent or to replace part of the esophagus.

Gastric ulcers are often treated by the same means used to treat GERD. In addition, antibiotics are used to eliminate any bacteria that may be the cause of the ulcers. Sucralfate may be used to form a barrier over the ulcer that protects it from stomach acid and allows it to heal.

Patients with pyloric stenosis normally require surgery to widen the canal leading from the stomach to the duodenum. In addition, those with intestinal malrotation may require surgery, depending on the severity of the condition. Surgery may also be required for patients with Meckel diverticulum if bleeding is a problem.

Cardiovascular treatment

In mild cases of cardiovascular involvement, no treatment plan is initiated other than to monitor the dysfunctions. Some septal defects may be asymptomatic and heal on their own. Since most of these abnormalities can lead to infective endocarditis, patients should be given antibiotics before undergoing dental procedures or surgeries.

KEY TERMS

Autosomal dominant—A pattern of inheritance in which one copy of a mutated gene on a non-sex chromosome is sufficient to cause disease.

Chromosomal aneuploidy—A condition in which the chromosomal number is either increased or decreased.

Clinodactyly—An abnormal inward curving of the fingers or toes.

Cohesinopathy—A condition, such as Cornelia de Lange syndrome, that affects the cohesion complex that separates chromosomes during cell division.

Fistula—An abnormal passage or communication between two different organs or surfaces.

Gastrointestinal reflux disease (GERD)—A chronic condition, usually accompanied by heartburn, that can damage the esophagus.

Haploinsufficiency—A condition caused by the loss of one copy of a gene.

Hypertrichosis—Excessive hair growth; also called hirsutism.

Infective endocarditis—An infection of the tissue lining the walls of the heart.

Oligodactyly—The absence of one or more fingers or toes.

Sporadic—Occurring at irregular intervals in no particular pattern or order.

Syndactyly—Webbing or fusion between the fingers or toes.

Synophrys—A feature in which the eyebrows join in the middle; also called blepharophimosis.

Teratogenic factor—Any factor that can produce congenital abnormalities.

For patients who develop congestive heart failure, a regimen of drugs known as beta blockers may be useful for slowing down the heart. Other drugs that may be used include diuretics, to prevent fluid retention, or ACE inhibitors.

For more serious cardiac involvement, surgery is recommended. Surgery for tetralogy of Fallot involves widening the pulmonary valve and repairing the ventricular septal defect. This surgery is normally performed on patients between the ages of eight months and three years. Ventricular septal defects can be repaired, usually with a synthetic patch. Atrial septal defects are normally performed by catheterization to

QUESTIONS TO ASK YOUR DOCTOR

- What are the factors on which preliminary and definitive diagnoses of Cornelia de Lange syndrome are based?
- Should my child have genetic testing for Cornelia de Lange syndrome? Should family members be tested?
- What are the characteristic symptoms of Cornelia de Lange syndrome?
- What factors determine how long children with Cornelia de Lange syndrome will live and their quality of life?
- What is the likelihood of having a second child with Cornelia de Lange Syndrome?

place a device between the atria in the septum. Patent ductus arteriosus correction is done by either ligating the vessel or cutting it off.

Hearing and visual concerns

Patients diagnosed with CdLS should be examined for hearing loss as soon as possible because of the likelihood of speech delay. Patients should be fitted with hearing aids and may be considered for pharyngeal-esophageal tubes.

It is important to identify vision problems early. Glasses may be necessary for nearsightedness. Children should be seen by an ophthalmologist in order to assess limitations and develop a treatment plan.

Other issues

CdLS-specific developmental charts and growth charts are available to guide treatments and therapies. Since development of speech is often delayed, children with CdLS should be seen by a speech pathologist at an early age. Alternative communication strategies, such as sign language, may be employed, depending on the level of speech development. Children and family members may also benefit from therapy available from a number of organizations. Patients may qualify for health-related support services from a variety of national organizations for retarded persons. Children with persistent behavioral problems such as hyperactivity, severe impulsive behavior, aggression, or self-injury may require specialist psychological or psychiatric treatment. CdLS also affects multiple oral structures, and early dental evaluation and

treatment are very important. Treatment for cleft palate may be required.

Prognosis

Patients with CdLS can live well into adulthood, although lifespan is typically shortened. Gastrointestinal and respiratory complications are the most common causes of death in patients with CdLS. Prognosis can be improved by early diagnosis and intervention. These two factors can influence not only patients' life expectancy but also quality of life for them, their family, and their caregivers.

Costello syndrome

Definition

Costello syndrome is an extremely rare genetic disorder caused by mutations in the *HRAS* gene. It affects many aspects of growth and development, and is characterized by newborn feeding problems, poor growth, loose and wrinkled skin, and mental retardation.

Description

The *HRAS* gene produces a protein called H-Ras that helps regulate cell growth and division. Costello syndrome results from mutations in *HRAS* that produce an overactive H-Ras protein that directs cells to constantly grow and divide. This apparently results in many of the characteristic features of Costello syndrome, although the exact mechanisms are unclear. H-Ras-promoted uncontrolled cell growth also can lead to the development of cancerous (malignant) and non-cancerous (benign) tumors. For this reason, *HRAS* is called an oncogene—a gene in which mutations can cause cancer.

H-Ras is a type of enzyme called a GTPase that converts a molecule called GTP into GDP. This acts as a switch, relaying signals from outside the cell to the cell nucleus to instruct the cell to grow or divide. The *HRAS* gene mutations responsible for Costello syndrome result in an H-Ras protein that is always turned on so that cells throughout the body grow and divide out of control. This abnormal process apparently leads to the other characteristics of Costello syndrome, including delayed development, intellectual disabilities, and distinct facial features, including a large mouth, loose skin folds, and very flexible joints. Children with Costello syndrome also commonly have structural heart defects, an abnormal heart rhythm, and an enlarged and weakened heart muscle.

KEY TERMS

Arrhythmia—Abnormal heart rhythm; examples are a slow, fast, or irregular heart rate.

Autosomal dominant—A pattern of inheritance in which one copy of a mutated gene on a non-sex chromosome is sufficient to cause disease.

HRAS—The gene encoding the H-Ras protein that helps regulate cell growth and division; mutations in *HRAS* can cause Costello syndrome.

Larynx—The voice box or the organ that contains the vocal cords.

Oncogene—A gene, such as *HRAS*, that can cause cancer if mutated.

Papillomatous papules—Skin-colored, raised bumps (not warts) found on the skin; most of these growths are benign (noncancerous) and rarely become malignant (cancerous).

Polyhydramnios—A condition in which there is too much fluid around the fetus in the amniotic sac.

Rhabdomyosarcoma—A malignant tumor of the skeletal muscle.

Somatic mutation—Sporadic mutation; a gene mutation that is not inherited from a parent carrying the mutation but rather occurs in an egg or sperm cell or during fetal development.

They are of relatively short stature and may have reduced levels of growth hormone.

From early childhood, patients with Costello syndrome are at increased risk for various cancers, as well as benign tumors called papillomas—small growths usually around the nose and mouth or anus. The most common childhood cancer associated with Costello syndrome is rhabdomyosarcoma, which originates in muscle tissue. Neuroblastomas that arise in developing nerve tissue have also been reported. Adolescents with Costello syndrome can be at risk for a type of bladder cancer associated with older adults. Individuals with Costello syndrome may also be at increased risk for thyroid, kidney, and other cancers.

Genetic profile

The capital letters in *HRAS* gene stand for “Harvey rat sarcoma viral oncogene homolog.” This gene is located on the short arm (p) of chromosome 11 at position 15.5 (11p15.5). At least 15 mutations in *HRAS* are known to cause Costello syndrome. These mutations change

single amino acids in an essential region of the H-Ras protein. More than 80% of Costello syndrome cases are caused by a mutation that changes the amino acid glycine to the amino acid serine at position 12 in the H-Ras protein (Gly12 Ser or G12S).

Costello syndrome is an autosomal dominant condition. This means that only one copy of a mutated *HRAS* gene is sufficient for the development of Costello syndrome, even when the second copy of *HRAS* is normal. Almost all known cases of Costello syndrome occur in children without a family history of the disorder; rather, they are new gene mutations—known as somatic or sporadic mutations—that were not inherited from a parent but that occurred in an egg or sperm cell, or during early embryonic or fetal development.

Some individuals who have been diagnosed with Costello syndrome do not have an identified mutation in the *HRAS* gene. It is possible that they may actually have Noonan syndrome or cardiofaciocutaneous (CFC) syndrome, which are caused by mutations in genes that interact with the H-Ras protein to control cell growth and division.

Demographics

In 1971 and 1977, Dr. J. Costello described the mental and growth delays and distinctive facial and skin features of the syndrome that carries his name. After these initial descriptions, there were no further reports of Costello syndrome until 1991. Costello syndrome is now estimated to affect 200–300 people worldwide, with an estimated prevalence ranging from 1 in 300,000 to 1 in 1.25 million people. It affects both males and females equally and most likely occurs in all racial and ethnic groups.

Signs and symptoms

The first signs of Costello syndrome may appear even before birth. Mothers carrying Costello syndrome babies may have polyhydramnios (an excess of amniotic fluid in the womb). This may be because of the fetus's poor swallowing ability. Many Costello syndrome babies are large at birth, especially with respect to weight, and have a large head. However, they begin life with severe feeding problems. They do not grow and thrive; rather, they lose weight and become quite ill. This poor growth continues until about two years of age. Then, for unknown reasons, growth, especially weight gain, begins to normalize. However, the children continue to grow slowly and will remain short throughout life. Most adults with Costello syndrome are approximately 4.5 ft. (1.5 m) tall. X-ray studies at different ages show that bone growth is delayed, leading to reduced height.

Infants with Costello syndrome have a slight downward slant of the eyes, full cheeks, thick lips, and an

upturned nose. The neck is short. The ears are low-set (below the level of the nose) with large, fleshy earlobes. These features seem to coarsen and become more noticeable over time. However, the signature feature of Costello syndrome is the soft, deeply wrinkled skin, especially on the hands and feet. This is evident at birth and becomes even more striking in the first few months of life. All individuals with Costello syndrome have deeply creased loose skin. Some physicians have described the distinct, deep creases in the skin as resembling “bathtub hands”—similar to the puffiness seen after soaking one's hands in water. Other skin characteristics may include dark-colored moles on the palms of the hands and the bottoms of the feet, brownish-colored birthmarks almost anywhere on the body, and small red marks on the surface of the skin caused by broken blood vessels. Unusual skin growths called papillomatous papules, which are skin-colored, raised bumps, form inside the nose and mouth, on the tongue, and around the anus in late childhood or early adolescence. These rarely become cancerous.

Most individuals with Costello syndrome have sparse, curly hair and a hoarse voice. The hair turns gray at a very early age, sometimes even during adolescence. Along with the loose wrinkled skin, the gray hair makes Costello syndrome patients appear much older than their age. The Costello syndrome voice, described as low and hoarse, may possibly be due to weakness in the tissues or muscles of the larynx.

All individuals with Costello syndrome have significant mental delays and delays in walking and talking. They are usually a few years behind other children their age. These learning disabilities continue as they get older and require special education. IQ testing shows mild to moderate retardation (IQs of 30–68). Although they have special needs, Costello syndrome individuals are outgoing, with friendly personalities, which helps them make the most of their abilities.

Other signs and symptoms of Costello syndrome may include:

- tight Achilles tendons
- weak muscle tone (hypotonia)
- a structural brain abnormality called a Chiari I malformation
- skeletal abnormalities
- dental problems
- vision problems

Diagnosis

The pattern of overgrowth in the womb, poor growth after birth, and short height is typical of individuals with Costello syndrome. However, the signs and symptoms

QUESTIONS TO ASK YOUR DOCTOR

- Are there prenatal signs or symptoms that might suggest that my child will be born with Costello syndrome?
- Should my child have genetic testing for Costello syndrome?
- Should other family members have genetic testing?
- What is the risk that my partner and I will have another child with Costello syndrome?
- What health problems will an infant with Costello syndrome likely experience?
- What ongoing treatments or other procedures will be needed to assist a child born with Costello syndrome?
